(1E $0630+178$ ), subsequently located to 3 arc $s$ using the high-resolution imager on the same telescope system. Most of the emitted X-ray photons have energies below 1 keV with little evidence for interstellar absorption, indicating that the X-ray object cannot be more than 200 pc distant. A subsequent 10 -hour observation with EXOSAT has confirmed the soft nature of the X-ray spectrum and a search for time variability is under way. A series of optical studies for this region of the sky has revealed a 21.3-magnitude point-like object, which is located at the edge of the error box of the Einstein satellite and which has an apparent lack of emission and absorption features, reminiscent of the Crab and Vela pulsars. Although the corresponding position on the Palomar sky survey is blank, a search of the 1955 Palomar plates by J. Bloeman of the Huygen's Observatory at Leiden has revealed an object, some 10 arc s away, which is not present in recent more sensitive (CCD) plates. The magnitude ( $M_{\mathrm{R}}$ $=20-20.5$ ) of the 1955 object is similar to that of the Einstein satellite's counterpart; if they are the same object, a proper motion of $0.37 \mathrm{arcs} \mathrm{yr}^{-1}$ and a distance of 100 pc
are implied. By contrast, a series of astrometric observations between November 1982 and October 1983 by J. Lecacheux and co-workers has set an upper limit of $0.2 \mathrm{arcs} \mathrm{yr}^{-1}$ on the proper motion of this object.
What is this source? The combination of its point-like nature and high $(\sim 1,000)$ ratio of X-ray to optical luminosity rules out most known classes of X-ray objects, with the exception of low-mass binary systems and pulsars. The former seems unlikely because the measured low visual magnitude would place it at a distance of $\sim 250 \mathrm{kpc}$ which is incompatible with the lack of X-ray absorption. In any case, a pulsar is a more attractive orthodox candidate because the two galactic COS-B sources so far identified are pulsars and both show excess $\gamma$-ray luminosities.

Paradoxically, radio searches of the error box of the COS-B satellite have pinpointed a number of possible counterparts, none of which pulsates or coincides with the source identified by the Einstein satellite. One promising radio candidate, discovered using the $100-\mathrm{m}$ Effelsberg telescope, has subsequently been identified
with the quasar $0630+180$ by the SAO/UAO Multiple Mirror Telescope. Should this distant quasar prove to be Geminga, at $L_{y} \geq 10^{49} \mathrm{erg} \mathrm{s}^{-1}$, it would be the most luminous source of high-energy photons known, assuming isotropic emission. Alternatively, if it is a highly collimated $\gamma$-ray jet beamed towards the Earth, its luminosity would not be so great.

Although there is still no solution to the riddle of Geminga ("the source that is not there" in Milanese dialect), the detailed multi-waveband searches have demonstrated that it is dominated by $\gamma$-ray emission. Furthermore, whether a neutron star or a quasar, it is highly likely that Geminga offers the uncommon possibility of looking straight down a cosmic $\gamma$-ray beam. Finally, it is clear that, in the absence of temporal correlations across the wavebands, the question of what is the counterpart to Geminga will only be answered by use of a future $\gamma$-ray telescope with much improved angular resolution.
A.J. Dean is at the Department of Physics, University of Southampton, Southampton SO9 5NH.

## Astronomy

## IRAS circulars 8 and 9

The source name consists of four parts: (1) the letters 'IRAS' to indicate the origin; (2) right ascension (RA) in hours and minutes and seconds; (3) declination ( Dec ) in decimal degrees, multiplied by 10 and then truncated (i.e. +32 deg 42.3 arc min becomes +327 ); (4) an appendix starting with ' P ' and followed by the number of the circular; this appendix stresses that the data are preliminary. Position is given at equinox 1950.0. The measurements have been made between epochs 1983.1 and 1983.4 (for circular 8, below left) and between epochs 1983.1 and 1983.7 (for circular 9, below right).

The sources in circular 9 (below right) were selected because their flux densities have ratios compatible with those of the OH IR star discussed in a forthcoming paper in the Astrophysical Journal Letters ( 15 March 1984)by Olnon et al. The list may contain planetary nebulae. The sometimes very large upper limits to the $100-\mu \mathrm{m}$ fluxes are due to high background at low galactic latitudes. Uncertain flux values are marked*. The sources were selected by H.I. Habing and F.M. Olnon, Sterrewacht, Leiden, Netherlands.

| Source | RA | Dec | Flux density (Jy) |  |  |  | Source | RA <br> $h \mathrm{mins}$ | Dec |  | Flux density (Jy) |  |  |
