Phytoplankton growth can be limited by numerous inorganic nutrients and organic growth factors. Using the subarctic diatom *Attheya sp.* in culture studies, we examined how the availability of vitamin B₁₂ and carbon dioxide partial pressure (pCO₂) influences growth rate, primary productivity, cellular iron (Fe), cobalt (Co), zinc (Zn) and cadmium (Cd) quotas, and the net use efficiencies (NUEs) of these bioactive trace metals (mol C fixed per mol cellular trace metal per day). Under B₁₂-replete conditions, cells grown at high pCO₂ had lower Fe, Zn and Cd quotas, and used those trace metals more efficiently in comparison with cells grown at low pCO₂. At high pCO₂, B₁₂-limited cells had ~50% lower specific growth and carbon fixation rates, and used Fe ~15-fold less efficiently, and Zn and Cd ~3-fold less efficiently, in comparison with B₁₂-replete cells. The observed higher Fe, Zn and Cd NUE under high pCO₂/B₁₂-replete conditions are consistent with predicted downregulation of carbon-concentrating mechanisms. Co quotas of B₁₂-replete cells were ~5- to 14-fold higher in comparison with B₁₂-limited cells, suggesting that >80% of cellular Co of B₁₂-limited cells was likely from B₁₂. Our results demonstrate that CO₂ and vitamin B₁₂ interactively influence growth, carbon fixation, trace metal requirements and trace metal NUE of this diatom. This suggests the need to consider complex feedback interactions between multiple environmental factors for this biogeochemically critical group of phytoplankton in the last glacial maximum as well as the current and future changing ocean.

Subject Category: microbial ecosystem impacts

Keywords: phytoplankton; iron; vitamin B₁₂; carbon dioxide; ocean acidification; trace metals

Introduction

Marine phytoplankton account for about half of global primary production (Behrenfeld and Falkowski, 1997), and depend on the availability of dissolved inorganic carbon, major nutrients and trace elements. Many eukaryotic phytoplankton also require a number of organic growth cofactors including cobalamin—vitamin B₁₂ (Provasoli and Carlucci, 1974)—a cobalt (Co)-containing molecule synthesized by many, but not all, bacteria and

archaea (Rodionov *et al.*, 2003). About half of cultured eukaryotic phytoplankton species, including many harmful algal bloom dinoflagellates, are unable to synthesize B₁₂ and thus require an exogenous supply (Provasoli and Carlucci, 1974; Croft *et al.*, 2005; Tang *et al.*, 2010). The renewed attention to B₁₂ over the past decade has led to numerous field studies that have demonstrated that vitamin B₁₂ is a limiting factor in a variety of marine ecosystems, including temperate and polar coastal waters (Sañudo-Wilhelmy *et al.*, 2006; Gobler *et al.*, 2007), iron (Fe)-limited/high-nutrient regimes of the Southern Ocean (Bertrand *et al.*, 2007) and the high-nitrate, low-chlorophyll (HNLC) Gulf of Alaska (Koch *et al.*, submitted).

Another factor potentially affecting phytoplankton growth that has recently received attention is the availability of dissolved inorganic carbon in the context of ocean acidification (reviewed by Hutchins *et al.*, 2009). Past glacial–interglacial variability in carbon dioxide partial pressure (pCO₂) based on

paleoclimate proxies (Petit *et al.*, 1999) and the future predicted anthropogenic rise in pCO₂ (Solomon *et al.*, 2007) could influence phytoplankton physiology and elemental requirements. For instance, a higher CO₂ availability could alleviate high metabolic energy and trace metal requirements of the carbon-concentrating mechanisms that supply CO₂ for photosynthesis (Raven, 1991; Morel *et al.*, 1994).

Despite the global importance of both vitamin B₁₂ and pCO₂ to phytoplankton metabolic pathways, virtually nothing is known about the possible interactions between these two critical factors. We tested the effects of B₁₂ and CO₂ availability on specific growth rates, primary productivity and the requirements of major nutrients (C, N and P) and Fe, as well as other trace metals (zinc (Zn), Co and cadmium (Cd)) in steady-state semi-continuous cultures of *Attheya sp.*, a centric diatom isolated from the Bering Sea (an Fe-limited HNLC region; Leblanc *et al.*, 2005). *Attheya sp.* belongs to the family Chaetocerotaceae, and was previously classified in the genus *Chaetoceros* (Crawford *et al.*, 2000), a biogeochemically important algal group that dominates blooms in coastal upwelling regions and in mesoscale and bottle Fe addition experiments (Hutchins and Bruland, 1998; de Baar *et al.*, 2005).

Materials and methods

Unialgal axenic *Attheya sp.* (CCMP207) stock cultures, isolated from the Bering Sea, were obtained from the Provasoli-Guillard Culture Collection of Marine Phytoplankton (West Boothbay Harbor, Maine, USA) and grown in microwave-sterilized media prepared from 0.2 µm-filtered natural seawater (collected using trace metal clean techniques). Media had Aquil concentrations of nitrate, phosphate and silicic acid with additions of 5 µM EDTA, 451 nM Fe, 80 nM Zn, 50 nM Co and no added Cd (Price *et al.*, 1988/89). Stock cultures were incubated at 3 °C with a 12h:12h light–dark cycle and an incident photon flux density of 80 µmol photons m⁻² s⁻¹. Although B₁₂ auxotrophy has not been evaluated for *Attheya sp.*, various centric diatoms including species from the same family, Chaetocerotaceae, have been found to require vitamin B₁₂ (Provasoli and Carlucci, 1974). Cultures were verified to be axenic by staining subsamples with 4',6-diamidino-2-phenolindole, followed by bacterial counts using epifluorescence microscopy directly before the final sampling.

Experimental treatments included trace metal clean vitamin B₁₂ additions of 500 and 10 ng l⁻¹ (370 and 7 pM) for the B₁₂-replete and B₁₂-limited cultures, respectively. The 7 pM vitamin B₁₂ was used for B₁₂-limited cultures because steady-state growth rates at that concentration were about half of maximum growth rate. Vitamin and nutrient stocks were cleaned of trace metals before use by passing

them through a column packed with Chelex-100 (Bio-Rad, Hercules, CA, USA; Price *et al.*, 1988/89). For both B₁₂ conditions, triplicate acid-washed polycarbonate bottles were equilibrated with commercially prepared air:CO₂ mixtures at three different CO₂ concentrations: 200, 370 and 670 p.p.m. pCO₂ (see below). In-line HEPA filters were used to avoid trace metal and bacterial contamination from the gas tanks or lines.

Trace metal clean semi-continuous culturing methods were used during acclimation periods and steady-state growth. Final sampling was carried out following 4–8 weeks of semi-continuous incubation after statistically invariant growth rates were recorded for at least three consecutive transfers. Cultures were grown semi-continuously to maintain cells in the exponential growth phase to avoid bias resulting from sampling during different growth phases in different experimental treatments. All medium handling, culturing and manipulation used careful trace metal clean methods under class 100 conditions.

Seawater medium pCO₂ in the experimental bottles was calculated throughout the experiment using measurements of pH and total dissolved inorganic carbon according to Dickson and Goyet (1994). To ensure that CO₂ levels remained constant during growth, the pH in each bottle was monitored daily using a microprocessor pH meter, calibrated with pH 4, 7 and 10 buffer solutions. Total dissolved inorganic carbon was measured via coulometry (model CM 140, UIC, Joliet, IL, USA). The calculated pCO₂ values (using CO2SYS; http://www.cdiac.ornl.gov/ftp/co2sys/CO2SYS_calc_XLS) from the final day of the experiment were 201 ± 13, 367 ± 21 and 671 ± 31 p.p.m. (Table 1); these treatments are referred to using rounded-off values of 200, 370 and 670 p.p.m. pCO₂.

Primary production was measured in triplicate using 24 h incubations with 3.7 kBq ml⁻¹ H¹⁴CO₃ under the appropriate experimental growth conditions of light and temperature for each treatment, followed by filtration and scintillation counting. Aliquots for analysis of particulate organic C and N were filtered onto pre-combusted 25 mm GF/F filters (Whatman, Maidstone, UK) and analyzed using a 4010 CHNS Elemental Combustion System (Costech, Valencia, CA, USA). Samples for particulate organic phosphorous were processed and analyzed spectrophotometrically. Details for these methods can be found in Fu *et al.* (2005, 2007; and references therein).

Particulate samples for trace metal analysis were filtered onto acid-washed 3-µm-pore-size polycarbonate filters (Millipore, Billerica, MA, USA), rinsed with oxalate reagent to remove extracellular trace metals (Tovar-Sanchez *et al.*, 2003), and Fe, Zn, Co and Cd were determined with a magnetic sector-field high-resolution inductively coupled plasma mass spectrometer (ICPMS) (Element 2, Thermo, Waltham, MA, USA). Procedural filter blanks were also subjected to the same storage, digestion,

Abbreviations: DIC, dissolved inorganic carbon; pCO₂, carbon dioxide partial pressure.

Seawater medium pCO₂ levels were calculated from measurements of pH and DIC from the final sampling day, but were consistent at or near these values throughout most of the experiment after a brief initial equilibration period (data not shown).

dilution and analysis processes, and these blank values were subtracted from sample measurements (Sañudo-Wilhelmy *et al.*, 2001). The digestion protocol consisted of sequential additions of ultra-pure HCl, HNO₃ and HF (Omnitrace Ultra; VWR, Westchester, PA, USA) and heating to 100 °C (Eggemann and Betzer, 1976).

The measured concentrations of particulate elements (C, N, Fe, Co, Zn and Cd) were normalized to P. Previous studies have demonstrated that phytoplankton cellular P quotas are usually not affected by changing pCO₂ (see review by Hutchins *et al.*, 2009). Cellular elemental 'quota' or 'content' are reported in this article interchangeably with 'requirement', although we acknowledge that cellular quotas could possibly be elevated by luxury uptake and/or storage of trace metals (for instance, Fe luxury uptake/storage; Sunda and Huntsman, 1995a; Marchetti *et al.*, 2009). Trace metal:C ratios were used in conjunction with specific growth rates to calculate net use efficiencies (NUEs; specific growth rate divided by trace metal:C ratio), representing how efficiently trace metals are used by cells for growth and C fixation (Raven, 1991). This treatment implicitly circumvents concerns about distinguishing trace metal 'content' from 'requirements', as it quantitatively links the trace metal quota of the cells to growth and photosynthetic rates. Significant differences in growth parameters, nutrient/trace metal quotas and trace metal NUE were tested using two-way analysis of variance and Student's *t*-test (SigmaStat, Ashburn, VA, USA).

Results

Effect of B₁₂ and pCO₂ variability on specific growth rates and primary production

Specific growth rates (Figure 1a) and ¹⁴C-based primary productivity (Figure 1b) of B₁₂-limited cells (grown at 7 pM B₁₂) were significantly lower (~40–60% lower) than B₁₂-replete cells (grown at 370 pM B₁₂) at all three pCO₂ concentrations (200, 370 and 670 p.p.m. pCO₂; $P < 0.05$). Specific growth rates and primary productivity of B₁₂-replete cells

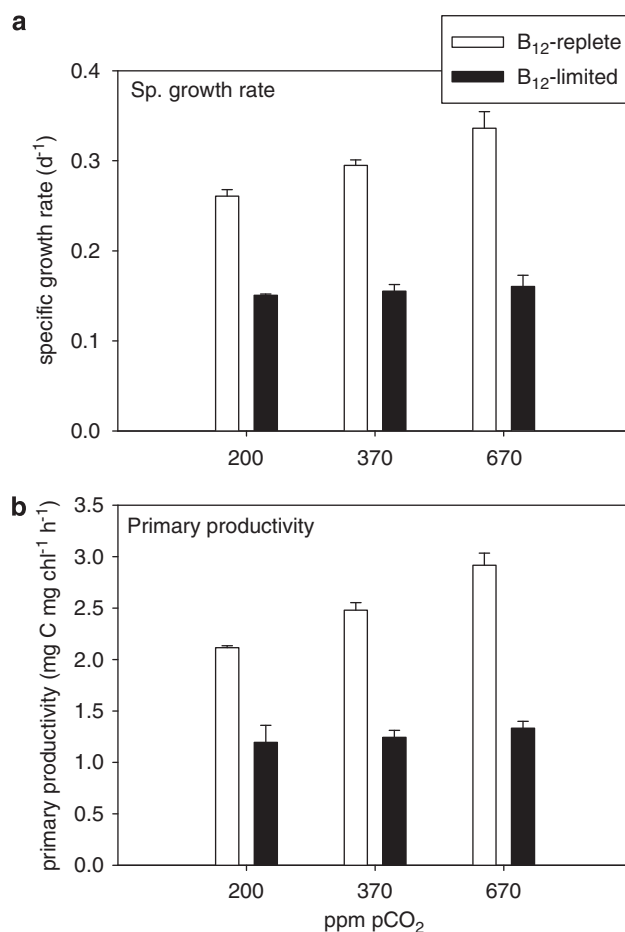

Figure 1 Growth parameters for *Attheya* grown at 200, 370 and 670 p.p.m. pCO₂ in B₁₂-replete (open bars) and B₁₂-limited cultures (filled bars). (a) Specific growth rates (per day) and (b) ¹⁴C-based primary productivity ($\mu\text{g C per } \mu\text{g chl per h}$). Error bars represent one s.d. ($n = 3$).

were positively correlated with pCO₂ ($r^2 = 0.99$ and 0.97 , respectively), and were ~30–40% higher at 670 p.p.m. compared with 200 p.p.m. pCO₂ ($P > 0.05$) (Figure 1). In B₁₂-limited treatments, specific growth rates and primary productivity were not significantly different among CO₂ treatments ($P > 0.05$) (Figure 1).

Effect of B₁₂ and pCO₂ variability on elemental ratios
Cellular molar C:P (Figure 2a) and N:P (Figure 2b) ratios of B₁₂-replete cells were significantly higher at 670 p.p.m. in comparison with the other two lower pCO₂ treatments ($P < 0.05$). Both C:P and N:P of cells from 670 p.p.m. pCO₂ treatments were also significantly lower in B₁₂-limited cells in comparison with B₁₂-replete cells ($P < 0.05$). There were no significant differences in C:P or N:P ratios between the three pCO₂ treatments in B₁₂-limited cultures (Figure 2; $P > 0.05$).

Fe quotas (mmol Fe:mol P) of B₁₂-replete cells were negatively correlated with pCO₂ ($r^2 = 0.92$), and Fe:P ratios at 370 p.p.m. (24 ± 11) and 670 p.p.m. (14 ± 1) were ~40% and ~70% lower, respectively, in comparison with Fe:P at 200 p.p.m. pCO₂ (41 ± 13 ; $P < 0.05$; Figure 3a). For B₁₂-limited cells, Fe:P was positively correlated with pCO₂ ($r^2 = 0.93$), and Fe:P of cells grown at 200 p.p.m. was ~50% and ~60% lower than that of cells at 370 and 670 p.p.m. pCO₂, respectively ($P < 0.05$). FeNUE (mol C fixed per mol Fe per day) of B₁₂-replete cells were comparable with FeNUE of B₁₂-limited cells at 200 p.p.m. pCO₂, but FeNUE of B₁₂-replete cells were ~4-fold and ~15-fold greater than B₁₂-limited

cells at 370 and 670 p.p.m. pCO₂, respectively ($P < 0.05$; Figure 4a).

Co:P ratios (mmol:mol) in B₁₂-replete treatments were negatively correlated with pCO₂ ($r^2 = 0.99$) (Figure 3b). In B₁₂-limited treatments, Co:P ratios were an order of magnitude lower ranging from 0.001 to 0.005 mmol:mol and were significantly lower in comparison with B₁₂-replete treatments at all CO₂ treatments ($P < 0.05$) (Figure 3b). Co:P in B₁₂-limited treatments were positively correlated with pCO₂ ($r^2 = 0.73$), and Co:P of cells grown at 670 p.p.m. pCO₂ were significantly higher than cells grown at 200 p.p.m. pCO₂ ($P < 0.05$; Figure 3b). CoNUE in both B₁₂-replete and B₁₂-limited treatments were comparable at 670 p.p.m. pCO₂, but CoNUE of B₁₂-limited treatments were ~5-fold and ~15-fold greater in comparison with B₁₂-replete treatments at 370 and 200 p.p.m. pCO₂ ($P < 0.05$), respectively (Figure 4b).

Zn:P and Cd:P ratios (mmol:mol) of B₁₂-replete and B₁₂-limited treatments displayed a similar negative and positive correlation with pCO₂, respectively, as observed for Fe:P (Figures 3c and d). ZnNUE and CdNUE were approximately threefold higher in 670 p.p.m. pCO₂/B₁₂-replete cells when compared with 670 p.p.m. pCO₂/B₁₂-limited cells ($P < 0.05$), but were not significantly different between B₁₂ treatments at 200 and 370 p.p.m. pCO₂ ($P > 0.05$) (Figures 4c and d).

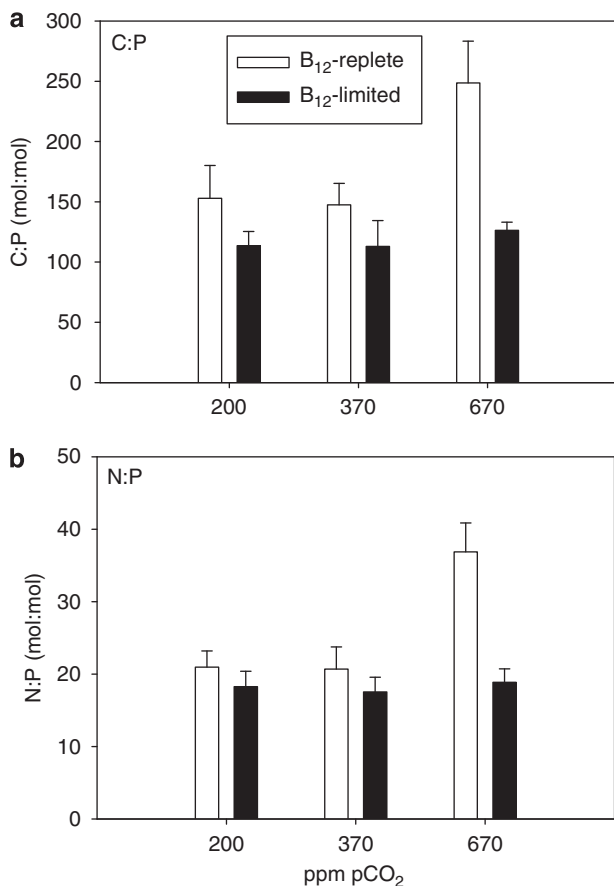

Figure 2 Particulate organic C and N normalized to P for *Attheya* grown at 200, 370 and 670 p.p.m. pCO₂ in B₁₂-replete (open bars) and B₁₂-limited cultures (filled bars). (a) C:P (mol:mol) and (b) N:P (mol:mol). Error bars represent one s.d. ($n = 3$).

Discussion

Growth rates, primary productivity and major elemental ratios

Phytoplankton B₁₂ limitation has been previously observed in natural phytoplankton assemblages in the US East Coast waters for the >5 μm size class as well as for specific taxa, such as diatoms and dinoflagellates (Sañudo-Wilhelmy *et al.*, 2006; Gobler *et al.*, 2007). B₁₂ limitation or B₁₂/Fe colimitation has also been documented in phytoplankton communities in HNLC areas of the Southern Ocean and the Gulf of Alaska (Panzeca *et al.*, 2006; Bertrand *et al.*, 2007; Koch *et al.*, submitted). Although *Attheya* sp. (CCMP207) has not been previously tested for dependence on vitamin B₁₂, our results (Figure 1a) clearly demonstrate growth rate limitation at B₁₂ concentrations similar to those measured in the coastal and open ocean (0.2–7 pM; Panzeca *et al.*, 2009) and in the range of previously reported B₁₂ half-saturation constants reported for other diatoms (~0.1–0.8 pM; reviewed by Droop, 2007). Specific growth rates and primary productivity were significantly lower under B₁₂ limitation at all pCO₂ concentrations (Figure 1). Similar reductions in growth rate and primary production by B₁₂ limitation have previously been reported for other diatoms in culture (Carlucci and Silbernagel, 1969; Swift and Taylor, 1974). In our semi-continuous culture design, regular dilutions were used to

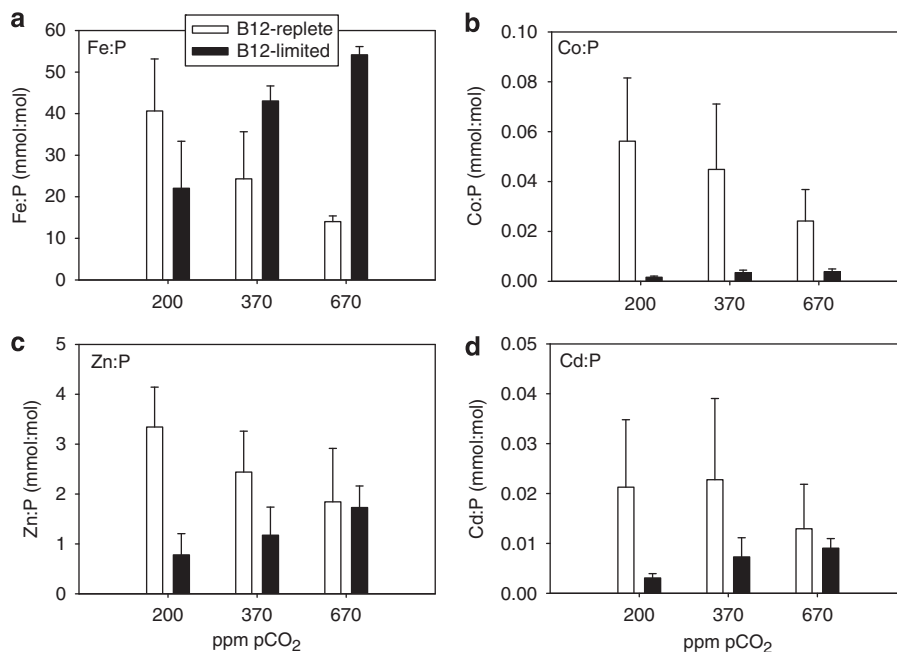

Figure 3 Fe, Co, Zn and Cd quotas for *Attheya* grown at 200, 370 and 670 p.p.m. pCO₂ in B₁₂-replete (open bars) and B₁₂-limited cultures (filled bars). (a) Fe:P (mmol:mol), (b) Co:P (mmol:mol), (c) Zn:P (mmol:mol) and (d) Cd:P (mmol:mol). Error bars represent one s.d. (n = 3).

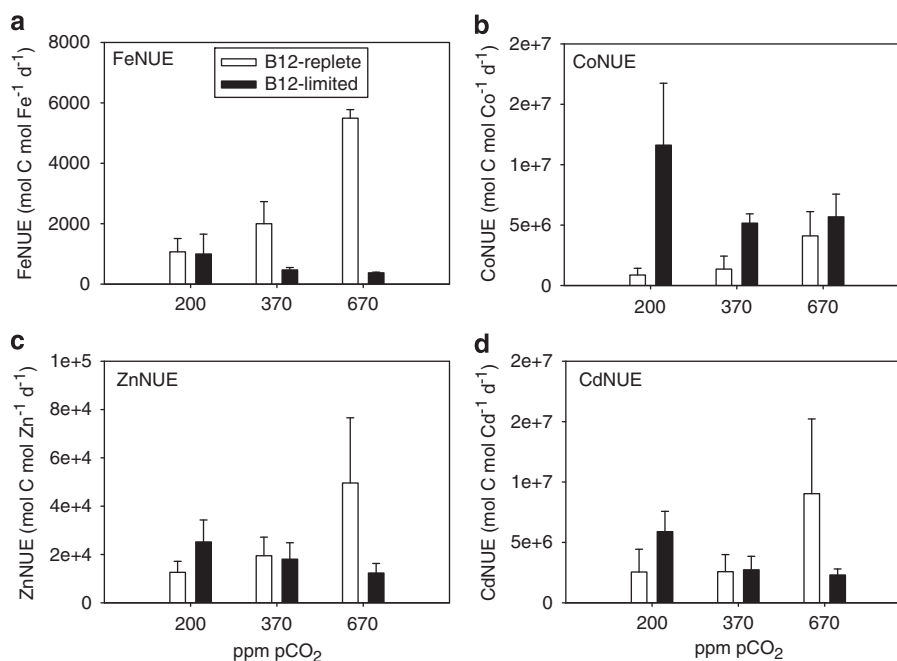

Figure 4 Trace metal NUEs (mol C fixed per mol metal per day) for *Attheya* grown at 200, 370 and 670 p.p.m. pCO₂ in B₁₂-replete (open bars) and B₁₂-limited cultures (filled bars). (a) FeNUE, (b) CoNUE, (c) ZnNUE and (d) CdNUE. Error bars represent one s.d. (n = 3).

prevent the cultures from entering stationary phase, thus prohibiting any evaluation of biomass yield limitation. Our experiments therefore examined rate limitation only, and future work using batch culture experiments is needed for direct comparisons with B₁₂ limitation of biomass yield (for example, Droop, 1957).

Furthermore, consistent with the influence of B₁₂ concentrations on growth and carbon assimilation rates, C:P and N:P ratios of B₁₂-limited cells were significantly lower in comparison with B₁₂-replete replicates at 670 p.p.m. pCO₂ (Figure 2). Potential changes in phytoplankton productivity, C:P and N:P at elevated pCO₂ could have large implications for

global nutrient cycles and the ocean's biological pump (Riebesell *et al.*, 2007; Hutchins *et al.*, 2009), and these empirical results suggest that vitamin B₁₂ availability could also have an important interactive role in modulating such stoichiometric shifts in the future high-CO₂ ocean.

Fe requirements and NUEs

Cells grown under B₁₂-replete/high-pCO₂ conditions had lower Fe quotas than B₁₂-replete/low-pCO₂ treatments (Figure 3a). The negative correlation between Fe requirements and pCO₂ could be a reflection of the lower external availability of Fe at high pCO₂—reduced uptake rates of Fe bound to model carboxylic acid and hydroxamate-type organic ligands were recently reported in diatom cultures at high pCO₂/low pH (Shi *et al.*, 2010). In our experiments, Fe was buffered by EDTA (via carboxylic acid moieties), and the lower observed Fe:P in B₁₂-replete cultures at 670 p.p.m. pCO₂ (Figure 3a) might be a result of lower Fe availability. However, Fe:P of B₁₂-limited/670 p.p.m. pCO₂-grown cells was the highest of all CO₂ treatments (Figure 3a), suggesting that another mechanism, in this case perhaps the influence of CO₂ on cellular Fe requirements, might have a larger effect than the reduction in Fe bioavailability.

A reduced Fe requirement for photosynthesis and respiration-generated energy to power carbonic anhydrases (CAs) or other carbon-concentrating mechanism-related cellular machinery could be reason for lower Fe:P (Figure 3a) and higher FeNUE (Figure 4a) of B₁₂-replete/670 p.p.m. pCO₂ cells. Theoretical calculations predict that cells saturated with CO₂ require less ATP and thus approximately one-third less Fe in the photosynthetic and respiratory electron transport chains (Raven, 1991). It is notable that in B₁₂-replete experiments, there is a counterintuitive relationship between Fe:P and physiological measurements—growth rate and primary productivity increase with pCO₂, whereas Fe requirements simultaneously decrease. Further studies assessing the relative importance of reduced *in situ* Fe bioavailability (Shi *et al.*, 2010) and lower cellular Fe requirements (this study) is warranted.

The synergistic relationship between vitamin B₁₂ availability and intracellular Fe quotas is not totally unexpected. Both Fe (Strzepek and Harrison, 2004) and phyloquinone (vitamin K₁; a macromolecule that requires B₁₂-dependent S-adenosyl methionine for its synthesis; Lohmann *et al.*, 2006) serve as electron carriers in photosystem I. Our empirical lab results (Figure 3a) suggest that Fe requirements of *Attheya* are lower (and FeNUE higher) when B₁₂ was replete at 370 and 670 p.p.m. pCO₂, perhaps because photosynthetic electron transfer is more dependent on phyloquinone. In contrast, under B₁₂-limited conditions, the Fe requirement of the organism was higher (and FeNUE lower), suggesting that electron transfer could be more dependent on

Fe –complexes, such as the cytochrome and ferredoxin. Although future studies will be needed to test the validity of this hypothesis, the 'photosynthetic architecture' of diatoms has been shown to depend on Fe availability (Strzepek and Harrison, 2004). The dominant electron transfer mechanism in photosystem I could also vary with ambient B₁₂ supply.

There are likely other indirect biochemical relationships between B₁₂/CO₂ availability and Fe requirements, as B₁₂, CO₂ and Fe are each intimately involved in multiple fundamental biochemical pathways, such as photosynthesis (see above), nutrient acquisition (for example, involvement of Fe in nitrate assimilation; Milligan and Harrison, 2000) and amino-acid synthesis (for example, B₁₂-dependent methionine synthase, metH; Croft *et al.*, 2005). Because B₁₂ is required for key enzymes, such as metH and methylmalonyl CoA mutase (Rodionov *et al.*, 2003; Croft *et al.*, 2005), Fe requirements may be affected downstream of where these enzymes are located in metabolic pathways. The role of B₁₂ in methionine synthesis could affect cell-wide processes because of the need of methionine for biosynthesis of proteins and various critical transmethylation reactions via S-adenosyl methionine (Fontecave *et al.*, 2004).

Co requirements and NUEs

Under B₁₂-replete conditions, Co:P ratios were ~5- to 14-fold higher in comparison with B₁₂-limited cells (Figure 3b), suggesting that Co-containing vitamin B₁₂ could comprise a significant fraction of the total cellular Co quota, and/or that B₁₂ limitation could result in lower Co requirements. In B₁₂-limited experiments, we calculated the percent of cellular Co that likely originates from assimilated B₁₂, assuming that the B₁₂ added to the media was completely bioavailable. If B₁₂ was fully utilized, Co from B₁₂ (one Co atom per B₁₂ molecule) accounted for ~78 to >100% of measured mean cellular Co (Table 2). When B₁₂ was limiting, CoNUE at 200 and 370 p.p.m. pCO₂ were relatively high because of the substantially lower Co quotas (Figures 3b and 4b). We are unable to make a similar

Table 2 Mean cellular Co and s.d. (in parentheses), percent of mean cellular Co from Co-B₁₂ and range (in parentheses), and mean dissolved Co utilization (calculated by difference) for B₁₂-limited cells, assuming B₁₂ is completely bioavailable and utilized

| pCO ₂ (p.p.m.) | Cellular Co (× 10 ⁻¹² M) | % From Co-B ₁₂ | % From dissolved Co |
|---------------------------|--|------------------------------|------------------------|
| 200 | 3.8 (1.5) | >100 | — |
| 370 | 8.8 (0.8) | 84 (73–95) | 16 |
| 670 | 9.4 (4.4) | 78 (54–148) | 22 |

Abbreviations: Co, cobalt; pCO₂, carbon dioxide partial pressure. [Co] contained in B₁₂ added to media was 7.4 × 10⁻¹² M; dissolved [Co] added to media was 5 × 10⁻⁸ M.

Co mass balance calculation for the B₁₂-replete cells, as our B₁₂-replete media had 370 pM Co–B₁₂ and 50 nM Co, which were both in excess of the measured cellular Co concentrations (62–133 pM; Table 2). In addition to Co in vitamin B₁₂, Co has also been identified as a metabolic substitute in diatoms for Zn in CA (Morel *et al.*, 1994; Sunda and Huntsman, 1995b).

Zn and Cd requirements and use efficiencies

When *Attheya* was grown under B₁₂-replete/high pCO₂, Zn:P and Cd:P ratios were low and ZnNUE and CdNUE were high (Figures 3c, d, 4c and d). Lower Zn:P is consistent with higher CO₂ availability and a decreased Zn requirement for Zn-containing CA used for catalyzing the conversion of HCO₃⁻ to CO₂ (Morel *et al.*, 1994; Lane and Morel, 2000a). Previous laboratory culture experiments with the diatoms *Thalassiosira weissflogii* and *Thalassiosira pseudonana* have also found higher Zn quotas of cells grown at lower pCO₂ in comparison with cells grown at present-day pCO₂ (Lane and Morel, 2000a; Sunda and Huntsman, 2005). Lower Cd:P ratios at high pCO₂ in B₁₂-replete treatments could be the result of the downregulation of a Cd-specific CA (Lane and Morel, 2000b; Lane *et al.*, 2005; Shi *et al.*, 2010).

In addition to CO₂, vitamin B₁₂ availability might also affect Zn-based CAs. Methionine, among two other amino acids, was found to be a critical component of a hydrophobic cluster on the C-terminal α -helix that predicated formation, and possibly function, of the β -type Zn-containing CA (PtCA1) of the diatom *Phaeodactylum tricornutum* (Kitao and Matsuda, 2009).

Ecological implications

Extrapolation from culture-based studies to natural ecosystems requires caution, but these results could have implications for altered (co)limitation patterns of phytoplankton in a changing ocean. At present-day pCO₂ (370 p.p.m.) and estimated pCO₂ before year 2100 (670 p.p.m.), B₁₂ limitation resulted in higher Fe quotas and lower NUE of Fe, Zn and Cd. Although diatoms in field experiments in the subarctic Pacific and Southern Oceans have been shown to be limited by Fe and/or B₁₂ (Bertrand *et al.*, 2007; Koch *et al.*, submitted), our experimental results imply that the consequences of low B₁₂ availability at current and future pCO₂ are a higher Fe requirement, lower growth/productivity and thus lower FeNUE. B₁₂ limitation of diatoms like *Attheya* could drive the subarctic Pacific and Southern Oceans (that are already relatively low in Fe) further toward B₁₂/Fe colimiting HNLC conditions. In contrast, if B₁₂ availability increases in the future ocean, a lower Fe requirement (and higher Fe/Zn/CdNUE) by diatoms might result in community shifts toward this group, a decoupling of their growth from Fe availability and strengthening of the biological C pump in these regimes.

In addition, *Attheya* belongs to a functional group of chain-forming centric diatoms that have been observed to proliferate in Fe addition bottle experiments and mesoscale Fe fertilization experiments in the HNLC regimes of the subarctic North Pacific, Southern Ocean and coastal California upwelling (Martin *et al.*, 1989; Hutchins and Bruland, 1998; de Baar *et al.*, 2005), and are believed to form resting spores that contribute to C export in the coastal subarctic and northeast Pacific (Grimm *et al.*, 1996; Saino *et al.*, 1998). Based on our experimental results, without an adequate supply of B₁₂, and despite a high availability of Fe, *Chaetoceros*-like diatoms would have a similar Fe requirement but use Fe much less efficiently to achieve only about half the growth and carbon fixation rates.

The present study highlights the linkages between organic growth factor limitation, trace metal requirements and NUE, and phytoplankton productivity under varying availabilities of pCO₂. For example, our results under conditions of the last glacial maximum suggest that increases in eolian Fe deposition alone to surface waters of HNLC areas during that period may not have been sufficient to reduce atmospheric CO₂ via the biological pump, contrary to Martin's 'iron hypothesis' (Martin, 1990). Our results showed that high primary productivity was only attained when B₁₂ was available. The relevance of Fe availability to the biological draw-down of atmospheric CO₂ during glacial periods has also recently been questioned by Boyd *et al.* (2010). Further work toward elucidating these types of interactions is needed to understand the biogeochemical consequences of natural and anthropogenic Fe fertilization in HNLC regimes, and the potential impacts of changing pCO₂ on global C cycling in the present-day and future ocean.
