Quasiparticle spin resonance and coherence in superconducting aluminium

C.H.L. Quay¹, M. Weideneder¹, Y. Chiffaudel¹, C. Strunk^{1,2} & M. Aprili¹

Conventional superconductors were long thought to be spin inert; however, there is now increasing interest in both (the manipulation of) the internal spin structure of the ground-state condensate, as well as recently observed long-lived, spin-polarized excitations (quasiparticles). We demonstrate spin resonance in the quasiparticle population of a mesoscopic superconductor (aluminium) using novel on-chip microwave detection techniques. The spin decoherence time obtained (~ 100 ps), and its dependence on the sample thickness are consistent with Elliott-Yafet spin-orbit scattering as the main decoherence mechanism. The striking divergence between the spin coherence time and the previously measured spin imbalance relaxation time (~ 10 ns) suggests that the latter is limited instead by inelastic processes. This work stakes out new ground for the nascent field of spin-based electronics with superconductors or superconducting spintronics.

Correspondence and requests for materials should be addressed to C.Q.H.L. (email: charis.quay@u-psud.fr).

Spin/magnetization relaxation and coherence times, respectively, T_1 and T_2 , initially defined in the context of NMR, are general concepts applicable to a wide range of systems, including quantum bits^{1–4}. If one thinks of spins as classical magnetic moments, T_1 is the time over which they align with an external magnetic field, while T_2 is the time over which Larmor-like precessions of the spins around the external field remain phase coherent². (T_1 is sometimes also called the longitudinal or spin-lattice relaxation time and T_2 the transverse relaxation time.) $T_1 \sim T_2$ for conduction electrons in most normal metals^{3,5–7}.

In a typical electron spin resonance (ESR) experiment, electrons are immersed in an external homogenous static magnetic field, H . Microwave radiation creates a perturbative transverse magnetic field (perpendicular to the static field) of frequency f_{RF} . The power $P(H, f_{\text{RF}})$ absorbed by the spins from the microwave field is determined, usually by measuring the fraction of the incident microwaves that is not absorbed, that is, either transmitted or reflected. When H is tuned to its resonance value, $H_{\text{res}} = 2\pi f_{\text{RF}}/\gamma$ —with γ the gyromagnetic ratio—the electron spins precess around H and $P(H, f_{\text{RF}})$ is maximal. $P(H, f_{\text{RF}})$ is proportional to the imaginary part of the transverse magnetic susceptibility, i.e. to $[(H - H_{\text{res}})^2 + (\frac{1}{\gamma T_2})^2]^{-1}$ in the case of a linearly

polarized field⁸. Thus, $T_2 = 2/(\gamma \Delta H)$, where ΔH is the full width at half maximum of the power resonance as a function of H .

At first glance, these ideas might seem to be irrelevant to conventional Bardeen–Cooper–Schrieffer (BCS) superconductors, as the BCS superconducting ground state is a condensate of Cooper pairs of electrons with opposite spins (in a singlet state)⁹. It has recently been demonstrated, however, that a non-equilibrium magnetization can appear in the quasiparticle (that is, excitation) population of a conventional superconductor, with T_1 on the order of several nanoseconds^{10–14}.

This raises the question of T_2 for these non-equilibrium quasiparticles; however, the short penetration depth of magnetic fields in type-I superconductors (~ 16 nm for bulk aluminium) creates difficulties for the observation of quasiparticle spin resonance (QSR): firstly, the signal is small—for normal metals, conduction ESR measurements are typically carried out on macroscopic foils tens of microns thick^{3,15}, and, second, the magnetic field in the superconductor is highly inhomogeneous¹⁶. (In type-II and unconventional superconductors, the entry of vortices into the sample can solve the first problem but not the second.)

In the following, we overcome these obstacles using thin-film samples and two novel on-chip microwave detection techniques

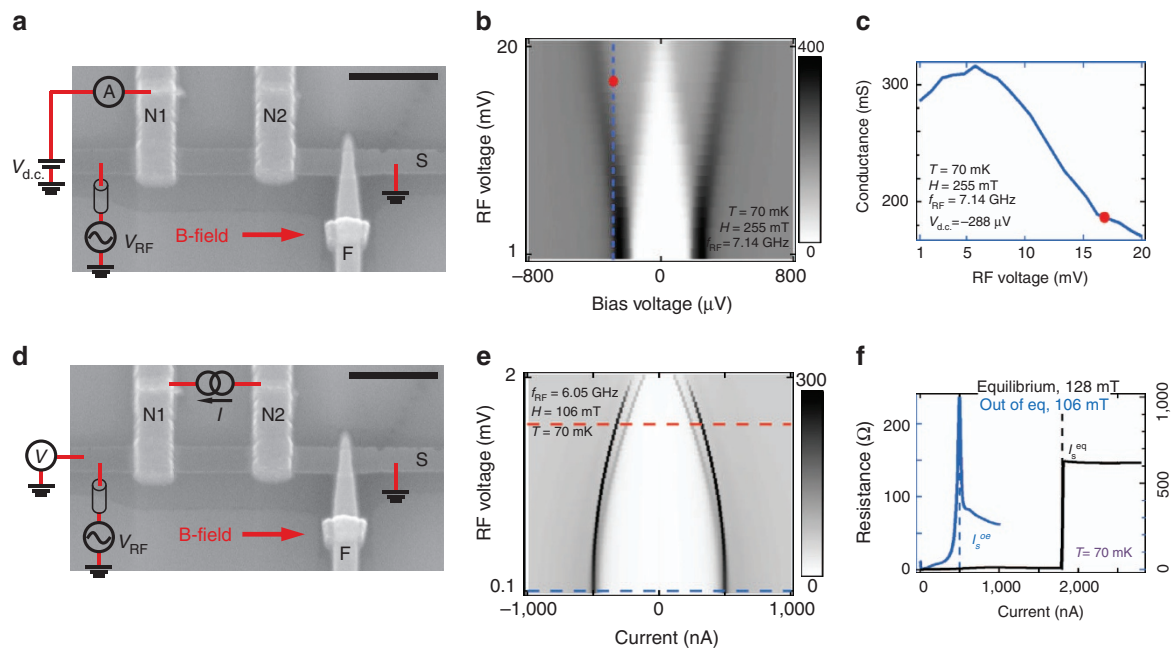

Figure 1 | Two on-chip microwave power detection schemes for superconducting (hybrid) devices. (a,c) Scanning electron micrograph of a device nominally identical to Device A (scale bar, $1\ \mu\text{m}$) and schematic drawings of the two measurement set-ups. (Data shown are from Device A unless otherwise stated.) In both cases, a static magnetic field, H is applied parallel to a superconducting bar (S, Al) and a sinusoidal signal of root mean squared amplitude V_{RF} and frequency f_{RF} in the microwave range applied across the length of S (with a lossy coaxial cable in series), resulting in a high-frequency field perpendicular to H . To detect the spin precession of the quasiparticles in S, two on-chip detection methods are used. (a) Detection scheme 1: a voltage $V_{\text{d.c.}}$ is applied between S and a normal electrode (N1, thick Al) with which it is in contact via an insulating tunnel barrier (I, Al_2O_3). The differential conductance $G = dI/dV_{\text{d.c.}}$ is measured, where I is the current between N1 and S. (b) G as a function of $V_{\text{d.c.}}$ and nominal V_{RF} (at the output of the generator and not accounting for attenuation in the lines). The red dot indicates the operation point of the detector for the data in Fig. 2: $V_{\text{RF}} = V_{\text{RF}}^0$, $V_{\text{d.c.}} = -288\ \mu\text{V}$. For any given frequency, we define V_{RF}^0 as the V_{RF} (at the output of the generator) at which the effective voltage at the device is the same as that for $f_{\text{RF}} = 7.14\ \text{GHz}$ and $V_{\text{RF}} = 16.81\ \text{mV}$. (See Supplementary Note 2 and Supplementary Fig. 2). (c) A slice of b at $V_{\text{d.c.}} = -288\ \mu\text{V}$ (blue dashed line in b) with the operation point indicated. (d) Detection scheme 2: a current $I_{\text{d.c.}}$ is injected along the length of S. We measure either the voltage V between the ends of the S bar or the differential resistance $R = dV/dI_{\text{d.c.}}$. We record in particular the switching current I_s at which S first becomes resistive. (e) R as a function of $I_{\text{d.c.}}$ and nominal V_{RF} (not accounting for attenuation in the lines). The switching current I_s at which S become resistive appears here as a peak in R . I_s can be seen to decrease monotonically with V_{RF} . The red dashed line indicates the operation point of the detector for the data in Fig. 3: $V_{\text{RF}} = 0.8V_{\text{RF}}^0$. (f) The blue trace is the first slice of e (blue dashed line in e) at $V_{\text{RF}} = 0.1\ \text{mV}$. The black trace is a two terminal measurement of the S bar, in the absence of microwaves, with a constant corresponding to the resistance of the lines subtracted. The difference in I_s between the two indicates that the S bar is strongly out of equilibrium in our second (switching current) detection scheme. (See Supplementary Note 4).

to perform QSR experiments on superconducting aluminium. We find $T_2 \sim 100$ ps $\ll T_1 \sim 10$ ns (ref. 12), in contrast to normal metals where $T_1 \sim T_2$, and identify spin-orbit scattering as the main decoherence mechanism.

Results

Devices and measurement set-up. Our devices are thin-film superconducting (S) bars, with a native insulating (I) oxide layer, across which lie normal metal (N) and either superconducting (S') or ferromagnetic (F) electrodes (in the cases of devices B and A, respectively). Here S and S' are both aluminium, I is Al_2O_3 , F is cobalt with an aluminium capping layer and N is thick aluminium with a critical magnetic field of ~ 50 mT (ref. 17). In all the data shown here, the N electrodes are in the normal state. The F electrodes are not used here, but rather in frequency-domain measurements of T_1 reported elsewhere¹⁰. Device A, lying atop a Si/SiO₂ substrate, is shown in Fig. 1. As in previous experiments, the NIS junctions have 'area resistances' of $\sim 6 \times 10^{-6} \Omega \text{cm}^2$ (corresponding to barrier transparencies of $\sim 1 \times 10^{-5}$) and tunnelling is the main transport mechanism across the insulator. (See Supplementary Information of ref. 12.) Measurements were performed at temperatures down to 60 mK, in a dilution refrigerator. On the basis of conductance measurements across the NIS junctions, S has a superconducting gap of $205 \pm 10 \mu\text{V}$ ($265 \pm 10 \mu\text{V}$) in device A (device B), corresponding to critical temperatures of 1.34 ± 0.07 K (1.75 ± 0.07 K) in the BCS theory.

A static magnetic field H is applied in the plane of the device and parallel to the S bar (Fig. 1a). S has a thickness of $d \sim 8.5$ nm (6 nm) for device A (device B), well within the magnetic field penetration depth λ , which we expect to be $\lesssim 315$ nm (375 nm) in our samples at 70 mK. (See Supplementary Note 1 and ref. 18 for details on this estimate.) The ratio of the orbital energy $\alpha = \frac{D(deH)^2}{6\hbar}$ to the Zeeman energy $E_z = \frac{1}{2}g\mu_B H$ is ~ 0.32 (0.22) for the quasiparticles in S in device A (device B) at 0.5 T \gtrsim the highest measured resonant magnetic field H_{res} . It is lower at lower fields. Therefore, the Zeeman energy is always dominant and we are in the 'paramagnetic limit'^{16,19,20}. Here D is the diffusion constant, e the electron charge, g the Landé g -factor, μ_B the Bohr magneton and \hbar Planck's constant. (See Supplementary Note 1 for details.) The data shown below are from device A unless otherwise stated.

A sinusoidal radio frequency signal of frequency f_{RF} and root mean squared amplitude V_{RF} is applied across the length of the S bar (via a lossy, that is, resistive coaxial cable). The resulting supercurrent flowing along the length of S serves primarily to produce the desired high-frequency magnetic field perpendicular to H ; secondarily, it also breaks some Cooper pairs and thus increases the quasiparticle population. Microwave radiation due to the supercurrent thus impinges on the quasiparticle spins in S. Some of this radiation is absorbed by the quasiparticle spins, and the rest transmitted to and absorbed by the surrounding environment. The 'transmitted radiation' can appear as a voltage across a tunnel junction between S and N; this is the basis of our first detection scheme (DS1; Fig. 1a). It can also be absorbed by the superconducting condensate, thus reducing the density of Cooper pairs and the current I_S at which S becomes resistive, known as the switching current; this is the basis of our second detection scheme (DS2; Fig. 1c). Both of our detection schemes for $P(H, f_{\text{RF}})$ are therefore entirely 'on-chip'.

In DS1 (Fig. 1a), we apply a bias voltage $V_{\text{d.c.}}$ across an NIS junction and measure its differential conductance $G = dI/dV_{\text{d.c.}}$ using standard lock-in techniques. (I is the current across the junction.) Figure 1b shows such traces as a function of V_{RF} , in which we see a flattening of the coherence peaks in a monotonic manner. (This is similar to the effect of classical rectification¹⁰.)

Figure 1c shows a slice of Fig. 1b at $V_{\text{d.c.}} = -288 \mu\text{V}$. G across the junction can be seen to be an effective microwave power meter at the chosen operating point (red dot). We define V_{RF}^0 (for any given frequency) as the reference V_{RF} (at the output of the generator) at which the effective voltage at the device is the same as that for $f_{\text{RF}} = 7.14$ GHz and $V_{\text{RF}} = 16.81$ mV. (See Supplementary Note 2 and Supplementary Fig. 2).

In DS2 (Fig. 1d), we measure the voltage-current characteristic of the S bar and record the switching current I_S . A current $I_{\text{d.c.}}$ is injected from one N electrode to another and the resulting voltage V across the length of the bar is measured. Figure 1e shows the differential resistance $R = dV/dI_{\text{d.c.}}$ of the S bar as a function of $I_{\text{d.c.}}$ and of V_{RF} . The peaks in these traces correspond to I_S . I_S can be seen to depend monotonically on V_{RF} and is thus also a good measure of the latter.

Our on-chip detection provides improved sensitivity compared with earlier work on the spin resonance of conduction electrons in normal metals (CESR)^{3,21}. Indeed, based on calculations for CESR measurements on macroscopic samples, it was previously thought that CESR signals in type-I superconductors would be

Figure 2 | Spin resonance in conductance across tunnel junction. (a) NIS junction conductance G as a function of H at $V_{\text{d.c.}} = -288 \mu\text{V}$ and $V_{\text{RF}} = V_{\text{RF}}^0$ for different f_{RF} . The black vertical line indicates the critical field of N. H_{res} and ΔH are obtained for each f_{RF} by fitting a Lorentzian with a linear background. The fit for $f_{\text{RF}} = 10.56$ GHz is shown (thin red line) and H_{res} indicated with a red vertical line. (b) H_{res} and ΔH the resonance linewidth (full width at half maximum) as a function of f_{RF} (red and blue circles, respectively). A linear fit to $H_{\text{res}}(f_{\text{RF}})$ data gives a Landé g -factor of 1.95 ± 0.2 . The black dots indicate values obtained at different powers or with the second detection scheme. (See Supplementary Note 3 and Supplementary Fig. 3). All dots and circles have been offset by 53 mT to account for a systematic shift in the applied magnetic field during the associated cooldown. The squares indicate values obtained from Device B, in which S is 6-nm thick.

unmeasurably small²². This is no doubt why, while a considerable amount of work has been done on the CESR in normal metals since the 1950s, to our knowledge only one such measurement has been performed on a bulk BCS superconductor (Nb) in the vortex state, close to the critical field^{23–25}.

Quasiparticle spin resonance. Having characterized our two microwave power meters, we now perform QSR measurements using each of them in turn, and compare the results of both.

In the first set of measurements, using DS1, we operate the NIS junction detector—which is to say measure the differential conductance $G = dI/dV_{d.c.}$ across it—at a fixed $V_{d.c.}$ of $-288 \mu\text{V}$ and $V_{RF} = V_{RF}^0$. ($G(V_{d.c.}, H)$ traces in the absence of microwaves are shown in Supplementary Fig. 1). As can be seen in Fig. 1c, at this operation point, small decreases in the absorbed power will result in a proportional increase in G . (It can also be seen that we remain in the linear regime in the measurements in Fig. 2).

Figure 2a shows $G(H)$ at several different f_{RF} . As expected, each trace shows a resonance, that is, an increase in $G(H)$ due to the fact that more power is being absorbed by precessing quasiparticle spins and therefore less appearing across the NIS junction. We determine H_{res} and ΔH by a Lorentzian with a linear-in- H background signal to these data. The background comes from magnetic-field-induced orbital depairing in the quasiparticle density of states. This measurement was repeated

at different f_{RF} ; H_{res} as a function of f_{RF} is shown in Fig. 2b. A linear fit to the data gives a g -factor of 1.95 ± 0.2 , consistent with previous measurements of electrons in Al in the normal state^{26,27}.

Note that ΔH may be larger than its intrinsic value if, for instance, the static field is inhomogeneous in the region of interest². This would then lead to an underestimate of T_2 . In our samples, however, $d/2 \ll \lambda$, as mentioned above. Thus, the magnetic field seen by the quasiparticles is homogeneous to $\lesssim 1.5\%$ in the superconductor, much smaller than the ΔH we measure, and our estimate of T_2 is unaffected by magnetic field inhomogeneity. This is confirmed by the fact that ΔH does not depend on H_{res} , as can be seen in Fig. 2b. Field homogeneity has been a challenge for both ESR and NMR measurements performed on macroscopic type-II superconductors. In these, specimen dimensions greater than λ mean that the field decays significantly within the specimen, and additional complications often arise from the presence of vortices.

In the second set of measurements, we use DS2. As can be seen in Fig. 1e, small decreases in the absorbed microwave power will result in a proportional increase in the switching current I_S . We first measure the differential resistance $R = dV/dI_{d.c.}$ of the S bar as a function of $I_{d.c.}$ and of H at $f_{RF} = 6.05 \text{ GHz}$, $V_{RF} = 0.8 V_{RF}^0$ (Fig. 3a). We observe an increase in I_S at $H = 0.17 \text{ T}$, which we identify as H_{res} —at this field, the quasiparticle spins enter into resonant precession, thus absorbing more microwave power. Less power is then transferred to the superconducting condensate and I_S increases.

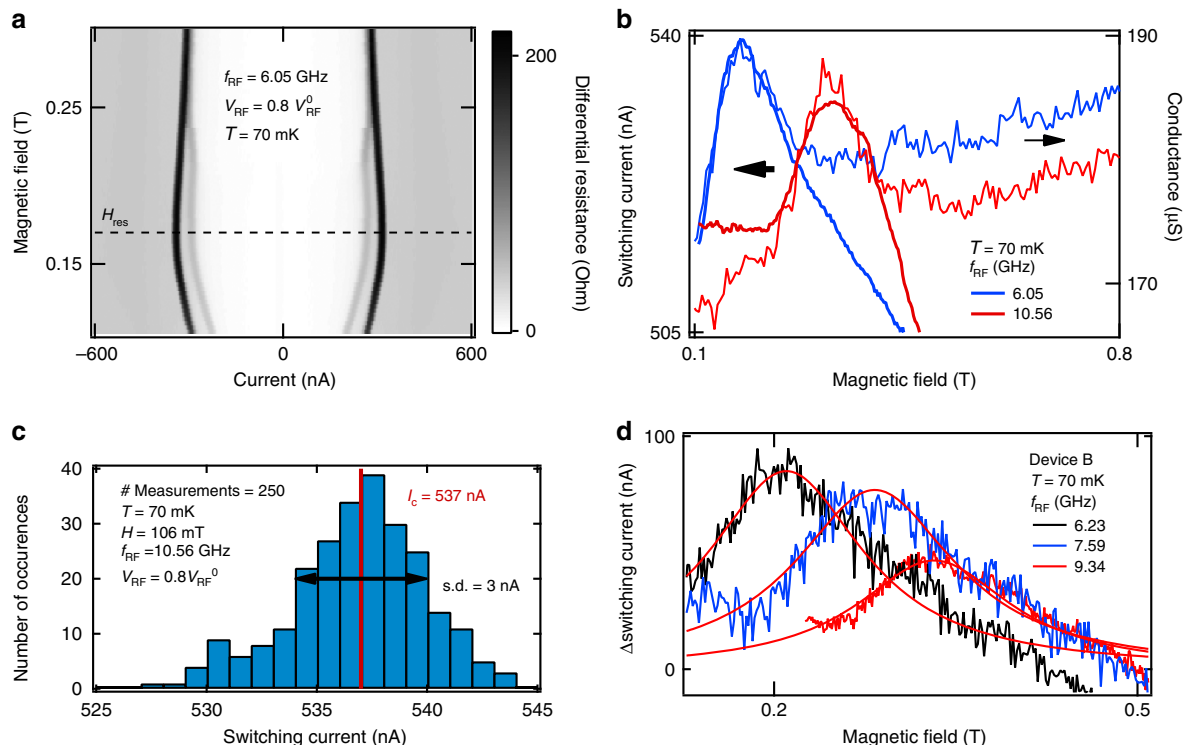

Figure 3 | Spin resonance in supercurrent, comparison of detection schemes. (a) Differential resistance R of the S bar as a function of H and $I_{d.c.}$ with $f_{RF} = 6.05 \text{ GHz}$, $V_{RF} = 0.8 V_{RF}^0$. At $H_{res} \sim 0.17 \text{ T}$, the resonant field, the switching current I_S can be seen to increase, indicating that less microwave power is being transmitted to the superconducting condensate as more power is absorbed by the quasiparticles in S. (b) Switching current I_S as a function of static magnetic field H for two different f_{RF} . (Here a slight change was made to the measurement circuit: With reference to Fig. 1d, the current is applied between N2 and F instead of between N1 and N2, hence the slightly higher I_S : the current injection electrodes are closer together.) Superimposed on these traces are the conductance traces from Fig. 2a at the same fields. H_{res} and ΔH can be seen to be similar for both measurement methods. The bold red trace has been offset downwards by 19 nA . (c) The switching currents in b are averages of ~ 200 measurements, with a s.d. of $\sim 3 \text{ nA}$. Here we show a histogram of 250 switching currents corresponding to the first point in the bold red trace in b. Current was driven long the length of the S bar and the voltage measured between N1 and N2. (Voltage and current leads are thus switched with respect to b). (d) Device B: switching current I_S as a function of static magnetic field H for three different f_{RF} , with a linear background subtracted (thick lines). H_{res} and ΔH obtained from the fits (thin red lines) are shown in Fig. 2b. These I_S values are averages of ~ 500 measurements.

In Fig. 3b, we show I_S as a function of H at two different frequencies. (I_S is the average of 200 switching current values obtained from $V(I_{d.c.})$ measurements.) The expected resonance appears at both frequencies. To compare results from the two different detection schemes, we superimpose on these traces data from Fig. 2a at the same f_{RF} . We see that both H_{res} and ΔH are the same for both detection schemes. We also verified that H_{res} and ΔH are independent of V_{RF} (see Supplementary Note 3, Supplementary Fig. 3 and black dots in Fig. 2b).

As DS2 is sensitive to a longer portion of the S bar compared with DS1, the agreement between the two detection schemes is further confirmation that the magnetic field is quite homogenous along the entire length of the S bar between the two N electrodes. Thus, our results for T_2 reported below should be reasonably close to the intrinsic value.

The spin coherence time T_2^S for 8.5-nm-thick superconducting aluminium (device A) is 95 ± 20 ps as determined from ΔH (the full width at half maximum of the resonance) in Figs 2a and 3b; this is fairly constant within the range of accessible fields (Fig. 2b). Measurements on device B, in which S is 6-nm thick yielded $T_2^S = 70 \pm 15$ ps (Figs 2b and 3d). Both the order of magnitude of T_2^S , as well as the fact that it is inversely proportional to the film thickness, are consistent with spin coherence limited primarily by τ_{so} , the Elliott–Yafet spin-orbit scattering time^{5,12,26–36}.

T_2^S is, however, relatively unaffected by the quasiparticle density: In device A, the linewidths measured by DS1 and DS2 are identical (Fig. 3b), whereas the quasiparticle density is estimated to be about two orders of magnitude higher in the supercurrent measurements (with injection across the tunnel junctions) than in the conductance measurements. (See Fig. 1f, Supplementary Note 4 and ref. 37.) In device B, the linewidth remained unchanged at temperatures of up to 600 mK and at injection currents (across an NIS junction) of up to 42 nA.

Equilibrium measurement of the spin-flip time. It is thus reasonable to compare T_2^S with an independent estimate of τ_{so} from $G(V_{d.c.})$ measurements across an SIS' junction in device B, following work by Tedrow and Meservey on Al thin films^{20,31,38}. (Here S' is a 8.5-nm-thick superconducting Al counter electrode.) In the absence of spin-orbit coupling, as spin is conserved in tunnelling between S and S', $G(V_{d.c.})$ shows a peak at $V_{d.c.} = (\Delta + \Delta')/e$ at all fields (with Δ (Δ') the superconducting energy gap of S (S')) and the Zeeman effect is effectively invisible. In the presence of small but finite spin-orbit coupling, spin mixing modifies the density states for each spin and leads to a small conductance peak at a lower voltage $V_{d.c.} = (\Delta + \Delta' - 2E_Z)/e$, whose height $\sim \tau_{so}$ (Fig. 4). (At very strong spin-orbit coupling, the two peaks merge; spin orbit then has the same effect on the conductance trace as a depairing magnetic field²⁰.) A fit using the BCS density of states and the theory outlined in refs 20,38 yields a spin-mixing parameter b of 0.018 ± 0.002 and $\tau_{so} = 45 \pm 5$ ps, which agrees well with T_2^S above, as well as previous measurements³¹ (Fig. 4).

Discussion

We now address the conspicuous divergence between T_2^S and T_1^S , the latter previously determined to be on the order of ~ 10 ns in films of similar thickness¹². In comparison, in normal Al, $T_1^N \sim T_2^N \sim 50$ ps in such films at 4 K (ref. 12). (Note that T_1^N depends on the film thickness^{12,26,27,33–36}.)

The striking effect can be understood by considering that spin imbalance (that is to say non-equilibrium magnetization) in superconductors can be thought of, in a simple picture, as having contributions from both a spin-dependent shift in the quasiparticle

Figure 4 | Independent measurement of spin mixing due to the spin-orbit interaction. Device B: conductance G as a function of voltage $V_{d.c.}$ across an SIS' junction, at different magnetic fields H (offset by $2.2 \mu\text{S}$). Apart from the principal, outer peak (OP) at $V_{d.c.} = (\Delta + \Delta')/e$, with Δ (Δ') the superconducting energy gap of S (S'), a smaller, inner peak (IP) can be seen at $\sim V_{d.c.} = (\Delta + \Delta' - 2E_Z)/e$, with E_Z the Zeeman energy. Fitting the data at $H = 1.28$ T to numerical calculations based on refs 20,38 (red dotted line) yields a spin-orbit time τ_{so} of 45 ± 5 ps. Numerical results for $\tau_{so} = 23$ and 69 ps are also shown (blue and black dotted lines, respectively). Lower inset: full-conductance trace at $H = 1.28$ T, showing all peaks. Upper inset: distance in $V_{d.c.}$ between outer and inner peaks at positive (red dots) and negative (blue dots) energies. The black dotted line, which has a slope of $2E_Z/e$, is a guide to the eye.

chemical potentials as well as spin-independent heating of the quasiparticle population^{11,39,40}. The former can be characterized by $\mu_s \equiv (\mu_{QP\uparrow} - \mu_{QP\downarrow})/2$ —with $\mu_{QP\alpha}$ the chemical potential of the spin- α quasiparticles—and the latter by an effective temperature T^* . (A more general description could be based on, for example, the quasiparticle distribution function for each spin).

T^* and μ_s should relax on different timescales, respectively, the inelastic scattering time τ_{in} and the spin-mixing time τ_{sf} (dominated in thin-film Al by τ_{so}). T_1^S is then the longer of τ_{in} and τ_{sf} , whereas T_2^S should be affected only by τ_{sf} but not $\tau_{in} - T_1^S$ and T_2^S in superconductors can thus be quite different. That the previously determined value for T_1^S is close to the inelastic relaxation time in Al, estimated to be ~ 5 ns from ref. 41 is consistent with spin relaxation being limited by τ_{in} and in particular quasiparticle–quasiparticle interactions^{41,42}. We note that the quasiparticle–phonon interaction time τ_{ep} —over which the whole system relaxes to equilibrium—has recently been determined in frequency-domain measurements in 20-nm-thick Al films at 100 mK to be $\sim 1.6 \mu\text{s}$ (ref. 43), much longer than both τ_{ee} and τ_{sf} . Thus, τ_{ep} should not be a limiting timescale for either T_1^S or T_2^S .

In contrast, spin accumulation in normal metals is impervious to T^* and is due only to μ_s . Spin relaxation in normal Al then occurs over τ_{sf} , which also governs spin coherence. Thus, $T_1^N \sim T_2^N \sim \tau_{sf}$ and indeed these terms are sometimes used interchangeably in the literature.

Our results are, in sum, consistent with spin-orbit scattering as the main spin decoherence mechanism in thin-film superconducting Al, and also with a picture in which T_1 and T_2 diverge in superconductors due to the plural sources of spin accumulation in these systems. This has implications for (coherent) computing possibilities using superconducting spintronic devices⁴⁴, and also raises new questions about the interactions between the two sources of spin imbalance in the simple picture presented above, as well as of both with the superconducting condensate^{39,40}.

Our methods for measuring the coherence time can in principle be extended to other superconducting materials—both conventional and unconventional—as long as they can be nanostructured. A little more speculatively, our work also calls to mind the NMR experiments performed on superfluid ^3He , which were critical for identifying its different phases and in particular their spin (triplet) structure; it opens up analogous perspectives in (unconventional) superconductivity, where (the manipulation of) the internal structure of Cooper pairs is now an active field of enquiry.

Methods

Sample fabrication and transport measurements. We fabricate our samples with standard electron-beam lithography and angle evaporation techniques in an electron-beam evaporator with a base pressure of 5×10^{-9} mbar. We first evaporated ~ 6 nm (~ 8.5 nm) of Al for device B (A), which is then oxidized at 8×10^{-2} mbar for 10' to produce a tunnel barrier, then 100 nm of Al at an angle. For device B, we then evaporated 8.5 nm at another angle. (In device A, 40 nm of Co and 4.5 nm of Al are evaporated at the second angle, but these electrodes were not used in this work.) All transport measurements were carried out in a ^3He - ^4He dilution refrigerator with a base temperature of 60 mK. Differential resistances were measured with standard lock-in techniques. The switching currents I_S reported here are the mean values of 200–500 measurements.

Acknowledgements

We thank H. Hurdequint and J. Fabian for helpful discussions on conduction ESR in normal metals and semiconductors, and R.W. Ogburn for helpful comments on the manuscript. This work was funded by an ANR Blanc grant (MASH) from the French Agence Nationale de Recherche. C.S. thanks the CNRS and the Université Paris-Sud for funding his sabbatical at the Laboratoire de Physique des Solides.

Author contributions

C.Q.H.L., M.W., Y.C. and M.A. fabricated the samples and performed the measurements. All the authors contributed to the data analysis and the writing of the manuscript.
