Microtubule (MT)–kinesin, a biomolecular motor system, is a promising candidate for construction of artificial biomachines for a variety of nanotechnology applications. An active self-organization (AcSO) method involving a specific streptavidin (St)–biotin (Bt) interaction has been developed to assemble MTs into a highly ordered structure by exploiting their motility on a kinesin-coated surface. Dynein is another biomolecular motor that moves along the MTs in the opposite direction from kinesin. Dynein has not yet been used to demonstrate the AcSO of MTs. In this study, we report the first successful demonstration of the AcSO of MTs on a dynein-coated surface to produce ring-shaped MT assemblies similar to those of kinesin. We found that ring-shaped MT assemblies obtained on dynein showed equal clockwise and counterclockwise rotational motion. This work will enrich the building blocks for designing future oriented motor protein-based artificial devices.

Keywords: active self-organization; dynein; microtubule; ring-shaped assemblies

INTRODUCTION

In living cells, biomolecular motor systems such as actin–myosin and microtubule (MT)–kinesin are important for activities such as motility,¹ cell division² and cellular transport.³ Biomolecular motor systems are well known for their high efficiency in converting chemical energy into mechanical work with high specific power (power per unit mass⁴), which is the reason that biomolecular motors have been proposed as the building blocks for nanobiodevices.

The highly processive biomolecular motor kinesin, which moves MTs toward their plus end, has widely been employed in nanoscale molecular shuttles,^{5,6} surface imaging tools,⁷ force measurements^{8,9} and lab-on-a-chip sensor devices. To integrate the MT–kinesin system into more ordered structures that might provide emergent functions as realized in natural systems, we have recently developed the method of active self-organization (AcSO) using a specific streptavidin (St)–biotin (Bt) interaction during the sliding motion of MTs on a kinesin-fixed surface in the presence of adenosine-tri-phosphate (ATP).^{10–12} This ATP-driven energy-dissipative self-organization process reaches a steady state that is far from equilibrium, differentiating it from conventional self-assembly processes that always tend to stay at an equilibrium state. This energy-dissipative AcSO method introduced a wide variety of motile MT assemblies of different shapes, such as bundles, networks and rings, in response to different experimental conditions, such as changes in MT and kinesin concentrations and St–Bt labeling ratio.^{13,14} Ring-shaped

MT assemblies were found to show rotational motion without changing the position of the center of mass, and because of the prospective utilization of continuous networks in future nanotechnological applications, these ring-shaped MT assemblies have attracted much attention.^{10–12,15–18}

Dynein is another biomolecular motor that moves along MTs using the chemical energy of ATP and critically differs from kinesin with respect to the direction of movement along MTs.^{19–21} Introduction of dynein to AcSO, which has not yet been addressed, will widen the future application of biomolecular motor systems. In this paper, we have demonstrated the first AcSO of MTs on a dynein-coated surface. We found that, as in the case of kinesin, AcSO using dynein also successfully produced ring-shaped MT assemblies under certain experimental conditions. Our work thus provides a means for enriching the collection of organized MT assemblies, which in turn will enhance the development of biomolecular motor-based artificial biomachines.

EXPERIMENTAL PROCEDURE

Tubulin purification

Tubulin was purified from porcine brain using a high-concentration 1,4-piperazinediethanesulfonic acid (PIPES; Sigma, Tokyo, Japan) buffer (1 M PIPES, 20 mM EGTA, 10 mM MgCl₂; pH adjusted to 6.8); high-molarity PIPES (HMPB) and BRB80 buffers (80 mM piperazine-N,N′-bis(2-ethanesulfonic acid), 2 mM MgCl₂ and 1 mM EDTA at pH 6.9) were prepared using PIPES, and the pH was adjusted using KOH.

Dynein purification

Cytoplasmic dynein was purified from porcine brain according to a published procedure.²² The anion exchange column (UnoQ-1; Bio-Rad Laboratories, Hercules, CA, USA)-purified cytoplasmic dynein peaks were pooled in HPLC buffer (35 mM tris(hydroxymethyl)aminomethane), 5 mM MgSO₄, 1 mM EGTA, 0.5 mM EDTA, 1 mM DTT, 10 mM ATP, pH 7.2) and supplemented with 24% sucrose. Dynein was flash-frozen and stored in liquid nitrogen.

Bt labeling of tubulin and stoichiometric estimation

Bt-labeled tubulin was prepared using biotin-XX-SE (Invitrogen/Life Technologies Japan, Tokyo, Japan) as previously described.²³ The labeling stoichiometry was ~0.6 per tubulin heterodimer, which was estimated by spectrometric titration using 2-(4'-hydroxyphenylazo)-benzoic acid (HABA) dye (Wako, Tokyo, Japan).²⁴

MT preparation

Bt and rhodamine-labeled MTs were obtained by polymerizing a mixture of Bt-tubulin and rhodamine-tubulin (Bt/Tub: 0.6; final tubulin concentration: 70 μ M) in a polymerization buffer (80 mM PIPES, 1 mM EGTA, 5 mM MgCl₂, 1 mM GTP, ~1% DMSO; pH adjusted to 6.8 using KOH) at 37 °C. After the prescribed incubation time (30 min, 24 h), the MTs were diluted to make the tubulin concentration 100 nM in a buffer (80 mM PIPES-2K, 1 mM EGTA, 1 mM MgCl₂, 0.13 M DMSO, 10 μ M taxol; pH adjusted to 6.8 using HCl).

Formation of ring-shaped MT assemblies through AcSO

To perform the *in situ* observation of MT-ring formation, a motility assay was carried out inside a humidified inert gas chamber system.²⁵ The inert gas chamber system consists of three main parts: a nitrogen gas cylinder, a humidity supporter and the chamber. The chamber has two segments: a base plate made of stainless steel and a cover plate made of poly(methyl methacrylate). The base plate contains a horizontally placed inlet and outlet, which facilitates the passage of nitrogen gas through the chamber and allow the flow rate of nitrogen gas to be controlled. To prevent the MTs from drying and to prevent damage by reactive oxygen species, we used the inert gas chamber system during motility assays.

Flow cells were prepared by placing a small cover glass (5 \times 5 mm²; Matsunami, Tokyo, Japan) on a large slide glass (40 \times 50 mm²) equipped with a pair of spacers to form a chamber of ~4 \times 5 \times 0.1 mm³ (*W* \times *L* \times *H*) in dimension. Plasma treatment was applied on the glass surface to obtain a hydrophilic surface.

The flow cell was filled with 5 μ L of casein solution (80 mM PIPES-2K, 1 mM EGTA, 1 mM MgCl₂, ~0.2 mg mL⁻¹ casein; pH adjusted to 6.8 using HCl) to prevent the adhesion of dynein active domains directly on the glass surface. After incubating for 3 min with casein solution to mask the glass surface, 5 μ L of 60 nM cytoplasmic-dynein solution (~80 mM PIPES, ~40 mM NaCl, 1 mM EGTA, 1 mM MgCl₂, 0.5 mg mL⁻¹ casein, 1 mM DTT, 10 μ M taxol, ~0.13 M DMSO; pH 6.8) was introduced and incubated for 3 min. The flow cell was washed with 5 μ L of motility buffer (80 mM PIPES, 1 mM EGTA, 2 mM MgCl₂, 0.5 mg mL⁻¹ casein, 1 mM DTT, 10 μ M paclitaxel, and ~0.13 M DMSO; pH 6.8). A diluted solution (5 μ L) of MTs (100 nM in motility buffer) was then introduced and incubated for 5 min, followed by additional washing with 5 μ L of motility buffer. The partial coverage of Bt on the MT surface with St (Wako) was performed by incubating the MTs with St solution (10 nM in motility buffer) for 3 min after fixing the MTs on dynein. Finally, the motility assay was initiated by applying 24 μ L of ATP solution (motility buffer supplemented with 5 mM ATP). All of the above procedures were conducted at room temperature.

Microscopic image analysis of motility assays

Rhodamine-labeled MT assemblies in motility assays were illuminated with a 100-W mercury lamp and visualized by an epi-fluorescence microscope with a Plan Apo 60 \times /1.40 objective (Nikon, Tokyo, Japan). Images were captured using a cooled-CCD camera (iXon; ANDOR Technology, Tokyo, Japan) connected to a PC.

Image analysis for motility assays

Movies and images of the motility assays captured by fluorescence microscopy were analyzed to determine the velocity of the MTs using the image analysis software (ImageJ, offered by the National Institutes of Health (NIH) and available at: <http://rsb.info.nih.gov/ij/>). Although the inner surface of the cover glass was observed through the glass, the captured images correspond to those observed from the reverse side of the flow cell. The clockwise (CW)/counter-clockwise (CCW) motion was discussed based on the captured images. In fluorescence microscopic images, one pixel corresponded to 0.11 μ m as a resolution. Velocity measurements were conducted using the software by manually tracking inhomogeneities, such as defects where MTs were partly wound down or differences in the fluorescence intensities of the MT rings. To measure the velocity of the MT rings, the tracks of the MTs in the six sequential images in 5 s intervals were manually detected using the software.

RESULTS AND DISCUSSION

Before performing the AcSO of MTs using dynein, we investigated the mobility of MTs, which is necessary for successful self-organization on a dynein-coated cover glass surface. In our study, the hydrophilicity of the glass surface appeared to be an important factor in ensuring the dynein-based motility of MTs. Strong hydrophobic interaction between the dynein and the cover glass surface seems to hinder the activity of dynein, perhaps due to the mode of adsorption of dynein that prevented MTs from approaching the active site of the motor protein and consequently resulting in failure of MT motility. The hydrophilicity of the glass surface was increased dramatically by applying a plasma treatment, as shown in Figure 1. To optimize the effect of the plasma treatment on the motility of MTs, we measured the velocity of MTs on cover glass surfaces that were plasma treated for different lengths of time (Figure 2). The velocity of MTs increased with time of plasma treatment and reached a plateau after 30 s of treatment. On the basis of this result, we consistently applied the plasma treatment to the cover glass surface for 60 s in this study.

AcSO of MTs was then performed on the plasma-treated cover glass surface coated with dynein by employing a specific St-Bt interaction through the *in vitro* motility assay. The AcSO of MTs performed on a dynein-coated cover glass surface is schematically shown in Figure 3. MTs were polymerized from tubulin monomers modified with Bt by incubating for 30 min at 37 °C, and the labeling stoichiometry was kept at 0.6 per tubulin heterodimer. After a flow cell was prepared, dynein was immobilized on the plasma-treated cover glass surface,

and MTs were then applied to the flow cell. On the basis of our previous report,²⁶ the MT concentration and St/Bt ratio were held at 100 nM and 1/10, respectively, to allow the formation of ring-shaped MT assemblies on the dynein-fixed surface. By adding ATP to the flow cell, we initiated the AcSO of the MTs. To permit the motility of the MTs for a longer amount of time, the flow cell was placed in an inert chamber after the addition of ATP and was incubated in the inert chamber by flowing humid nitrogen.^{27,28} The AcSO of the MTs was monitored under a fluorescence microscope, and sample observation was performed 1 h after ATP addition. Figure 4 shows a representative fluorescence image of the MT assemblies after 1 h of ATP addition. As shown in the figure, most of the MTs were found to form ring-shaped structures. The number density of the ring-shaped MT assemblies was 6.87 per 100 μm^2 , which was almost unchanged even after performing the AcSO for >1 h. This result indicates that MT ring formation reached a stable state by 1 h of AcSO. The percentage of ring-shaped MT assemblies showed that rotational motion was almost 100% (movie is available in Supporting information/movie 1). The mean velocity of the ring-shaped MT assemblies was found to be $0.04 \pm 0.002 \mu\text{m s}^{-1}$. A histogram of the inner diameter of the ring-shaped MT assemblies is shown in Figure 5, with a mean diameter of $4.86 \pm 3.29 \mu\text{m}$. Next, we investigated the direction of the rotational motion of those ring-shaped MT assemblies. We previously reported²⁶ that ring-shaped MT assemblies formed through AcSO on a kinesin-coated cover glass surface showed preferential rotational motion

Figure 4 Fluorescence microscopy image of the ring-shaped microtubule (MT) assemblies formed through the active self-organization (AcSO) on a dynein-coated surface. A full color version of this figure is available at *Polymer Journal* online.

(CW:CCW = 21:79). In that report, MT filaments were prepared by incubating tubulin monomers for 30 min at 37 °C, and the same conditions were used in the present work. However, as shown in Figure 6, ring-shaped MT assemblies obtained on the dynein-coated surface showed no preference in the direction of rotational motion. The percentages of ring-shaped MT assemblies rotating in CW and CCW directions were found to be almost equal. We also previously reported that ring-shaped MT assemblies obtained through AcSO on kinesin showed preferential rotation in the CCW direction (CW:CCW = 73:26) when the AcSO was performed using MT polymerized for 24 h at 37 °C. In the case of dynein, we observed that the ring-shaped MT assemblies obtained through the AcSO of MTs prepared by polymerizing for 24 h at 37 °C did not show any preferential rotation, CW:CCW = 40:60 (Figure 6). Thus, results obtained in the present study using dynein are in contrast to the results observed in the previous report using kinesin.²⁶ Moreover, we also observed no difference in the velocity of the ring-shaped MT assemblies moving in CW and CCW directions on the dynein-coated surface, and this result was consistent with that obtained in the case of kinesin.²⁶ Next, the rotational direction and inner diameter of the ring-shaped MT assemblies formed on a dynein-coated surface were compared with the aforementioned results of the previous study (Figure 7). As shown in this figure, any obvious change in the distribution of the inner diameters of the rings moving CCW and CW cannot be found. Previously, it was shown that on a kinesin-coated surface, the direction of the rotational motion of ring-shaped MT assemblies could be tuned from CCW to CW by using structure-controlled MTs.^{26,29} However, in the present study, ring-shaped MT assemblies formed on a dynein-coated surface did not show any directional preference despite the use of structure-controlled MTs. The different behaviors of ring-shaped MT assemblies observed in this and the previous study could be explained by the different interaction mechanisms of kinesin and dynein with MTs. Kinesin is known to be a motor protein that moves along the MT in a highly coordinated manner because of its high processivity. In contrast, the less processive dynein has been known to show a highly variable stepping pattern.^{30,31} MT is a cylindrical protein composed of protofilaments (PFs) of α - and β -tubulin subunits where longitudinal interactions between the subunits are basically hydrophobic, and lateral interaction of inter-PFs is electrostatic due to the interactions

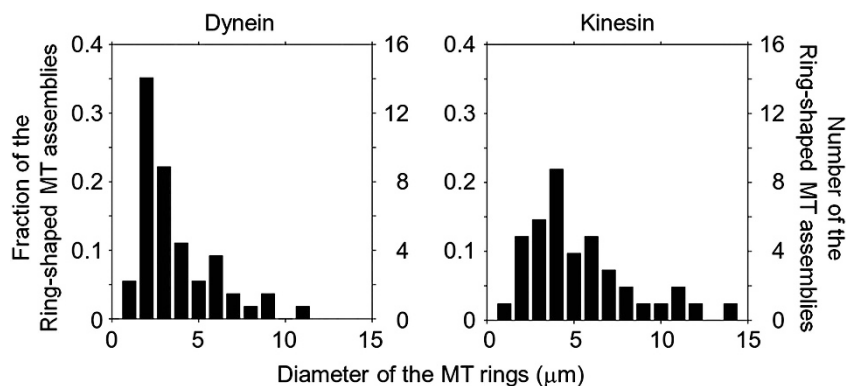

Figure 5 Size distribution of ring-shaped microtubules (MTs) formed through the active self-organization (AcSO) on dynein- and kinesin-coated surfaces. MTs polymerized for 30 min at 37 °C were used in these experiments.

Table 1 Summarized data on the velocity, inner diameter and direction of rotation of ring-shaped MT assemblies formed through AcSO on dynein- and kinesin-coated surfaces

Incubation time	Dynein		Kinesin	
	30 min	24 h	30 min	24 h
Velocity ($\mu\text{m s}^{-1}$)	0.03 ± 0.02	0.07 ± 0.05	0.20 ± 0.04	0.24 ± 0.04
Inner diameter (μm)	4.87 ± 3.22	4.14 ± 0.30	4.56 ± 2.52	5.82 ± 2.97
Rotation (CCW/CW (%))	40/60	33/67	21/79	74/26

Abbreviations: AcSO, active self-organization; CCW, counterclockwise; CW, clockwise; MT, microtubule.

of amino acids. The longitudinal interaction is affected by temperature and pH change, whereas the lateral one is affected by a change in the dielectric constant of the medium.³² The incubation time for polymerizing MTs is also important for allowing the MTs to reach their most energetically favorable configuration.³³ It has been reported that the number of PFs settled within a lattice of MTs is responsible for the left- or right-handed supertwist of MTs, minimizing the restoring force in the lattice.³⁴ In our previous study, we reported that with an increase in incubation time during MTs polymerization, the number of PFs within the MTs lattice shifted toward larger values. This increase in the number of PFs is correlated with the shift of left-handed supertwist in the MT lattice toward a right-handed supertwist. In this study, as shown in Figure 8, an MT with a left- or right-handed supertwist shows axial rotation (green arrow) when moving over processive motor protein.²⁹ This axial rotation is assumed to be superimposed on the linear motion (blue arrow), generating a torque (violet arrow) on the MT that leads to bending of the front segment of MT. The handedness of the torque might finally determine the direction of rotation of ring-shaped MT assemblies formed. In the case of a less processive motor protein, the supertwist structure of MTs might have a less pronounced effect in determining the handedness of torque on moving MTs. Consequently, the bending direction of the MT tends to be more stochastically averaged, and the ring-shaped MT assemblies showed unbiased rotational motion.

We also found that the inner diameter distribution of the ring-shaped MT assemblies formed on dynein (mean inner diameter = $4.13 \pm 2.22 \mu\text{m}$) was almost the same as that of assemblies formed on kinesin (mean inner diameter = $5.82 \pm 2.97 \mu\text{m}$). It is unclear why smaller rings were formed on dynein. Further investigations will be performed in future work. We have summarized data on

the velocity distribution, inner diameter and direction of rotational motion of ring-shaped MT assemblies formed on a dynein-coated surface using MTs prepared by polymerizing tubulin for 30 min and 24 h at 37 °C. We also compared our data with that obtained from the AcSO using kinesin (Table 1).

In conclusion, for the first time, we have successfully demonstrated the AcSO of MTs on a dynein-coated cover glass surface. The AcSO produced ring-shaped MT structures that showed non-preferential rotational motion. Our work brings variation to the collection and design of organized MT assemblies that should foster the development of biomolecular motor-based artificial biomachines.
