Abstract

Collagen plays a key role in normal and malignant tissue homeostasis. While the prognostic significance of collagen fiber remodeling in invasive breast cancer has been studied, its role in ductal carcinoma in situ (DCIS) remains poorly defined. Using image analysis, we aimed to evaluate the prognostic significance of the geometric characteristics of collagen surrounding DCIS. A large well-characterized cohort of DCIS comprising pure DCIS ($n = 610$) and DCIS coexisting with invasive carcinoma ($n = 180$) were histochemically stained for collagen using picrosirius red. ImageJ software was used to assess collagen density, degree of collagen fiber dispersion and directionality in relation to DCIS ducts' boundary. We developed a collagen prognostic index and evaluated its prognostic significance. A poor index was observed in 24% of the pure DCIS and was associated with determinants of high-risk DCIS including higher nuclear grade, comedo type necrosis, hormonal receptor negativity, HER2 positivity and high proliferation index. High collagen prognostic index was associated with the collagen remodeling protein prolyl-4-hydroxylase alpha subunit 2 and the hypoxia-related protein hypoxia inducible factor 1 α . DCIS coexisting with invasive breast cancer had a higher collagen prognostic index than pure DCIS ($p < 0.0001$). High index was an independent poor prognostic factor for DCIS recurrence for all recurrences (HR = 2.3, $p = 0.005$) and just invasive recurrences (HR = 3.4, $p = 0.003$). Interaction between collagen prognostic index and radiotherapy showed that the index was associated with poor outcome even with adjuvant radiotherapy ($p = 0.0001$). Collagen reorganization around DCIS is associated with poor outcome and provides a potential predictor for disease progression and resistance to radiotherapy. Mechanistic studies are warranted to decipher the underlying mechanisms.

Introduction

The key difference between invasive breast cancer and ductal carcinoma in situ (DCIS) is the destruction of the surrounding basement membrane and invasion of the malignant cells into the surrounding stroma accompanied by desmoplastic reaction. However, studies have shown that

changes in the surrounding tumor microenvironment including infiltrating immune cells, stromal cells, and extracellular matrix composition occurs early in carcinogenesis much before malignant cells invade the surrounding stroma [1–5]. More so, these changes may provide a surrogate to predict tumor behavior and potential outcomes [5–7]. One of the major limitations of currently available clinicopathological indices and molecular signatures to predict DCIS risk is the underestimated role of microenvironmental factors. Therefore, despite advances in management modalities, a considerable percentage of DCIS are either over- or undertreated. In addition, most molecular studies that compared the genetic profiles of DCIS and invasive breast cancer report a high degree of similarity [8, 9], creating a compelling need to decipher the role of the tumor microenvironment in DCIS behavior.

Collagen is the main constituent of extracellular matrix and plays a crucial role in tissues homeostasis [10]. There are many types of collagen with varied localizations and functions in normal and pathological conditions [2, 10]. The role of collagen in cancer development is not solely related to its chemical composition or signaling interaction but is mainly linked to its physical properties and geometric characteristics in relation to the tumor cells [4, 11–13]. Recent advances in imaging techniques and specific histochemical staining of collagen have spurred an increased interest to discover its physical roles and biological functions [12, 14–16]. In invasive cancers including breast cancer, studies have shown that densely aligned collagen is associated with poor outcome, and various tumor-associated collagen signatures have been described to assess the collagen organization surrounding invasive breast cancer [11]. There is a dearth of studies deciphering the role of collagen in DCIS; hence, more investigations are needed to evaluate its prognostic significance. While an earlier study has shown association of aligned collagen with other determinants of DCIS aggressive behavior, no statistically significant association with disease recurrence or progression was reported [6]. In the current study, we hypothesized that collagen reorganization surrounding DCIS is linked to aggressive behavior. We have developed an imaged-based collagen prognostic index that relies on three factors: the directionality of collagen fiber relative to DCIS boundary, collagen density and dispersion using a large cohort of DCIS.

Material and methods

Study cohort

A large well-characterized and annotated cohort of DCIS including pure DCIS ($n = 776$) and DCIS mixed with

invasive breast cancer (DCIS-mixed) ($n = 239$) diagnosed between 1990 and 2012 at Nottingham City Hospital, Nottingham, United Kingdom was used [17]. To avoid selection bias, the DCIS-mixed cohort was selected with clinicopathological features comparable to the pure cohort regarding age at diagnosis, DCIS nuclear grade, and the presence of comedo-type necrosis. All demographic, clinical, histological, management information was collected. Breast-conserving surgery was the primary surgical option for 70% of cases; however, due to close or positive surgical margins, a considerable percentage of patients underwent completion mastectomy; half of the cases were treated by mastectomy as the final operation. Data about the molecular classes, tumor infiltrating lymphocytes density [7], as well as the key regulator of collagen biosynthesis and remodeling prolyl-4-hydroxylases alpha subunit 2 [10] and the hypoxia-related marker hypoxia inducible factor 1 α were available. In brief, the molecular classes were defined based on the immunohistochemistry using estrogen (ER) and progesterone (PR) receptor, the human epidermal growth factor receptor 2 (HER2) and Ki67 proliferation index. ER and PR were considered positive if >1% of tumor cells showed nuclear staining [18] while HER2 positivity was defined when more than 10% of tumor cells showed strong complete membranous staining (+3 score). Chromogenic in situ hybridization was used to determine the gene amplification status in borderline cases (+2 score) [19]. The proliferation index was defined as low when <14% of cells showed nuclear staining for Ki67 [20]. Hypoxia-inducible factor 1 α was evaluated using immunohistochemistry and was considered positive when >1% of tumor cells showed nuclear staining as previously described [21]. Dense tumor infiltrating lymphocytes DCIS was defined in DCIS as an average number of ≥ 20 lymphocytes/duct [7]. Follow-up data were collected and local recurrence-free interval was defined as the time (in months) between 6 months after the primary DCIS excision and the development of ipsilateral recurrence (either as DCIS or invasive breast cancer). Cases undergoing completion re-excision due to margins' involvement or presence of residual tumor within the first 6 months of the primary operation were not considered as disease recurrence. Contralateral disease following DCIS diagnosis was not accounted as a recurrence and these patients were censored at the time of the development of the contralateral cancer. Within a median follow-up period of 103 months (range 6–240), 83 cases (11%) developed a recurrence in the pure DCIS cohort with 30 DCIS (36%) and 53 invasive recurrence (64%) [10, 22]. Most recurrences ($n = 66$) developed in patients treated with breast-conserving surgery alone.

Histochemical collagen staining with picrosirius red

Tissue microarrays were prepared from both cohorts as previously described [17]. Briefly, 1 mm punch sets were used to construct the tissue microarray using an automated GRAND MASTER 2.4-UG-EN tissue microarray machine. For better representation of cases with heterogeneous DCIS histological patterns and/or nuclear grade, multiple cores were sampled from all representative areas.

Picrosirius red solution was prepared by mixing 0.5 g of Sirius Red (Direct red 80, Cat#365548, Sigma-Aldrich, Darmstadt, Germany) with 500 ml of saturated aqueous solution of picric acid (Cat# P6744-1GA, Sigma-Aldrich, Darmstadt, Germany). Briefly, tissue microarrays sections (4 μ m) were deparaffinized and rehydrated and immersed in the picrosirius red solution for 60 min. Physical removal of excess stain was carried out by vigorous slide shaking followed by gentle blotting against soft filter paper. Slides were washed in two changes of acidified water, dehydrated in three changes of 100% ethanol, cleared in xylene, mounted and cover-slipped. Using light microscopy, epithelial cells were stained yellow while the collagen fibers stained red.

Image acquisition

The stained tissue microarrays were scanned using a high-resolution digital scanner (NanoZoomer; Hamamatsu Photonics, Welwyn Garden City, UK), at $\times 20$ magnification. For obtaining the images for subsequent analysis, individual tissue spots were exported as JPEG (8-bit) files at $\times 20$ magnification (1368 \times 768 pixels). Multiple spots were exported for each core to represent the whole tissue. To improve the reliability of the study, cores with less than 15% area of stroma were excluded from the analysis. All excluded cases were unbiased with respect to clinicopathological features.

Image analysis

The image analysis was carried out using the Fiji package of ImageJ (NIHR public domain), which is available for free download at (<https://imagej.nih.gov/ij/download.html>). Individual tissue spot JPEG files were imported into ImageJ and was split into RGB (Red, Blue, Green) channels. The image segmentation of tumor from stroma was carried out on the green color space; the red and blue channels were discarded. The segmentation to identify objects of interest was carried out by adjusting the grayscale data to a binary image with foreground pixels of interest set to red (pixel signal intensity of 0) and background pixels set to white (maximum 8-bit intensity of

255). The pixel intensity threshold for classifying all pixels as either foreground or background was defined automatically using the ImageJ histogram thresholding feature. To decrease background noise, all images were adjusted to a threshold of 150. Fields of interest (specialized stromal collagen surrounding DCIS ducts) [23] were identified by manually delineating of multiple squares, 400 \times 400 μ m each in dimension (i.e. equivalent to 2 high power fields of the surrounding collagen), with their bases touching and parallel/tangential to the duct boundary at the area of contact. Several nonoverlapping areas were marked per image to segment the surrounding stroma, resulting in >100 fields (average 120 fields) of interest delineated per core. Features were extracted by measuring the pixel numbers for any particles in the final image using the automated tools in ImageJ. Features extracted included the directionality of collagen fibers, i.e. the angle of the adjacent collagen fibers in each square relative to the angle of the tangent (duct boundary); collagen fibers dispersion, i.e. the arrangement of fibers relative to each other; and solidity representing the collagen density. Data were recorded in degree ($^{\circ}$) for directionality and dispersion while pixels were used for solidity measurement. Each field of interest was analyzed separately and the average reading for each tissue core was considered as the final score for analysis. Moreover, cases with multiple cores were scored and the average of the final scores for each core was used for the analysis. Figure 1 and Supplementary Fig. 1 show a schematic representation of the image analysis process.

Calculation of collagen prognostic index score

Each parameter was categorized into three scores (1, 2, and 3) using cut-offs generated from X-tile bioinformatics software (Yale University, version 3.6.1) [24] based local recurrence-free interval in the pure DCIS cohort (Supplementary Table 1). Score 3 directionality indicated more perpendicular collagen fibers to duct boundary, Score 3 solidity related to dense collagen fibers while Score 3 dispersion referred to lower degree of collagen fiber dispersion i.e. collagen fibers parallel to each other. Collagen prognostic index was calculated according to the equation:

$$\begin{aligned} \text{Collagen prognostic index} = & \text{collagen directionality score}(1 - 3) \\ & + \text{collagen solidity score}(1 - 3) \\ & + \text{collagen dispersion score}(1 - 3). \end{aligned}$$

The generated score range was 3–9, and was divided into three prognostic groups based on X-tile software, whereby a score of 3 or 4 is the good prognostic group, 5–7 for

Fig. 1 Diagram shows the different parameters assessed to evaluate the collagen characteristics surrounding DCIS. Green squares refer to the fields of interest for analysis ($400 \times 400 \mu\text{m}$ surrounding the DCIS boundary and note that all squares are aligned touching and parallel to imaginary tangential line to the duct boundary). **a** Perpendicularly arranged collagen fibers relative to duct boundary. **b** Parallel arranged fibers towards the duct boundary. **c** Collagen fibers arranged parallel to each other (lower dispersion) while **d** randomly arranged fibers (higher dispersion). **e** Dense collagen fibers and **f** scanty collagen fibers. During the analysis the three parameters were assessed per each field of interest (square) and the final average value was used in the analysis. DCIS ductal carcinoma in situ

intermediate and score 8 or 9 indicates the poor prognostic group (Supplementary Table 1).

Statistical analysis

Statistical analyses were performed using SPSS v21 (Chicago, IL, USA) for Windows. Spearman's Rho test was used to correlate between the different assessed parameters. Association between collagen prognostic index and its different parameters and clinicopathological parameters was performed using chi-square, Mann–Whitney and Kruskal–Wallis tests (for categorical and numerical data respectively). Univariate survival analysis against local recurrence-free interval was carried out using log rank test and Kaplan–Meier curves. Cox regression model was used for multivariate analysis and to evaluate the interaction between radiotherapy and collagen prognostic index regarding the recurrence. For all tests, a two-tailed p value of less than 0.05 was considered as statistically significant.

Results

Distribution of collagen prognostic index parameters and groups

The final number of cases suitable for scoring was 424 pure DCIS and 149 DCIS coexisting with invasive breast cancer after unbiased exclusion of uninformative cores (lost, folded and those containing $<15\%$ stroma area). The distribution of collagen prognostic index and the three collagen geometric parameters are summarized in Supplementary Table 2. The median directionality and dispersion angles in the pure DCIS were 19.6° (range 1–85) and 16.7° (range 5–58), respectively, while the median solidity was 0.5 (range 0.001–0.9) and the median collagen prognostic index score was 6 (range 3–9). The distribution of all parameters was unimodal. The poor collagen prognostic index group represented 24% of the cohort with a similar percentage of DCIS in the good prognostic group (23%). Figure 2 shows various patterns of collagen arrangement surrounding DCIS. We found a positive linear correlation between high collagen solidity and perpendicular or oblique collagen arrangement related to the DCIS ducts' boundary ($r=0.5$, $p<0.0001$, Spearman's correlation). However, the degree of collagen dispersion showed a negative linear correlation with both collagen solidity ($r=-0.3$, $p<0.0001$, Spearman's correlation) and directionality ($r=-0.3$, $p<0.0001$, Spearman's correlation).

The proportion of cases with a high collagen prognostic index score (poor prognostic group) was higher in DCIS coexisting with invasive breast cancer than pure DCIS (38% and 24% respectively; $\chi^2=36.5$, $p<0.0001$) (Table 1). Similar results were observed when the score was analyzed using a numerical scale ($p<0.0001$) (Supplementary Table 3). Comparable results were observed for all index parameters, whereby DCIS coexisting with invasive carcinoma showed a higher extent of perpendicular collagen fibers in relation to DCIS boundaries and with collagen fibers more often arranged in parallel (lower dispersion) than pure DCIS either in categorical groups or using the numerical scores (Supplementary Tables 4 and 5). The proportion of DCIS-coexisting with invasive breast cancer showed denser collagen fibers was slightly higher than pure DCIS (58 vs. 50%) which was not statistically significant ($p=0.364$). Figure 3 illustrates the distribution of collagen prognostic index parameters within pure DCIS and DCIS-invasive breast cancer cohorts.

Significance of collagen prognostic index expression in pure DCIS

Poor collagen prognostic index was associated with other clinicopathological determinants of poor prognosis in DCIS (Table 1), including higher nuclear grade ($p<0.0001$),

Fig. 2 Example of collagen fiber arrangement in two DCIS cases. **a** and **b** represent a case surrounded by dense collagen with lower dispersion (parallelly arranged collagen fibers all over the duct perimetry) and different directionalities, where collagen fibers delineated in **(b)** with black square show parallel arrangement relative to duct boundary (the tangential line), the fibers in the green square show more perpendicular arrangement relative to the tangential line touching the duct boundary. **c** and **d** represent DCIS surrounded by scanty randomly distributed collagen fibers with varied directionality relative to tangential line to the duct boundary. (**a** and **c** are DCIS sections stained with picosirius red, while **b** and **d** are the images generated from ImageJ software). DCIS ductal carcinoma in situ

presence of comedo-type necrosis ($p < 0.0001$), hormonal receptor negativity ($p = 0.032$, $p = 0.029$ for ER and PR, respectively) and HER2 positivity ($p = 0.003$). Luminal A DCIS (ER+ and/or PR+, HER2- with $< 14\%$ proliferation index) had lower collagen prognostic index scores where 67% of cases belonged to the good prognostic group ($p = 0.037$). Moreover, poor collagen prognostic index was associated with other microenvironmental and stromal factors associated with poor DCIS prognosis such as dense tumor infiltrating lymphocytes [7] ($p = 0.016$), high levels of prolyl-4-hydroxylases alpha subunit 2 expression ($p < 0.0001$) which is a collagen remodeling protein which was previously reported to be associated with poor outcome in DCIS [10]. We validated our results by analyzing the numeric collagen prognostic index scores and found comparable results (Supplementary Table 3). Furthermore, collagen directionality, dispersion and solidity scores were analyzed individually with other clinicopathological parameters and the results are summarized in Supplementary Table 4 (for categorical groups) and Supplementary Table 5 (for continuous scores).

Outcome analysis

High collagen prognostic index was associated with shorter DCIS local recurrence-free interval either for all

recurrences (DCIS or invasive breast cancer) (HR = 2.0; 95% CI = 1.3–3.1; $p = 0.002$) and for invasive recurrences alone (HR = 3.1; 95% CI = 1.6–5.5; $p = 0.0003$) (Fig. 4). When analysis was confined to patients treated with breast-conserving surgery, similar results were obtained where poor collagen prognostic index was associated with worse outcome for all recurrences (HR = 2.1; 95% CI = 1.4–3.1; $p = 0.001$) and for invasive recurrences (HR = 3.0; 95% CI = 1.6–5.4; $p = 0.0003$) (Fig. 4). Collagen prognostic index was associated with poor outcome regardless of the DCIS nuclear grade, whereby poor collagen prognostic index was associated with shorter local recurrence-free interval either for all recurrences or invasive recurrences only (Fig. 5) for both high-grade DCIS and non-high-grade DCIS (low and intermediate DCIS were combined together due to the small number of events in the former group). Moreover, evaluation of the interaction between collagen prognostic index and radiotherapy (collagen prognostic index \times radiotherapy) using a Cox regression model showed that higher collagen prognostic index was significantly associated with shorter local recurrence-free interval even with radiotherapy (HR = 1.8, 95% CI = 1.3–2.3; $p = 0.0001$). Analysis of the individual index parameters (collagen directionality, dispersion, and solidity) showed significant associations with disease recurrence (Supplementary Fig. 2). Forest plots for univariate analysis of other clinicopathological parameters and

prognostic factor for DCIS recurrence in patients treated with breast-conserving surgery regardless of other known determinants of high-risk DCIS either for all recurrences (HR = 2.3, 95% CI = 1.3–4.2; $p = 0.005$) or invasive recurrences only (HR = 3.4, 95% CI = 1.5–7.6; $p = 0.003$) (Table 2).

Discussion

Precise assessment of DCIS risk is still challenging despite advances in high-throughput molecular techniques. None of the currently available clinicopathological-based nomograms and indices [25–28] or molecular signatures such as Oncotype DX DCIS [29] provide a reliable and clinically valid tool to predict DCIS risk of progression and/or recurrence to improve personalized management. The biological and clinical heterogeneity of DCIS coupled with underestimation of the important role of the tumor microenvironment in disease behavior are potential reasons for this lack of accuracy. Cancer is not exclusively a disease of malignant cells, but also involves crosstalk between

tumor, stromal cells and other components of the surrounding microenvironment. Thus, studying the role of DCIS microenvironment and its interaction with the tumor cells could resolve the DCIS management dilemma and provide an adequate and reliable risk stratification model [1, 5, 30–32].

Extracellular matrix and its main constituent, collagen, plays a key role in normal mammary gland development [33]. Interestingly, increased breast tissue density, caused mainly by increased collagen deposition, is a strong risk factor for breast cancer development with high breast density carrying a two- to sixfold increase in breast cancer risk compared to women with normal breast density which is almost as high a risk factor as *BRCA1* and *BRCA2* mutations [4, 34]. It is reported that DCIS arises more commonly in dense regions of the breast [4, 35]. While was thought that collagen provided a natural physiological barrier against tumor invasion, recent studies have provided concrete evidence on the key role of that collagen dynamic changes (collagen deposition, degradation, reorganization and remodeling) in carcinogenesis, tumor maintenance and progression through its role in cellular adhesion,

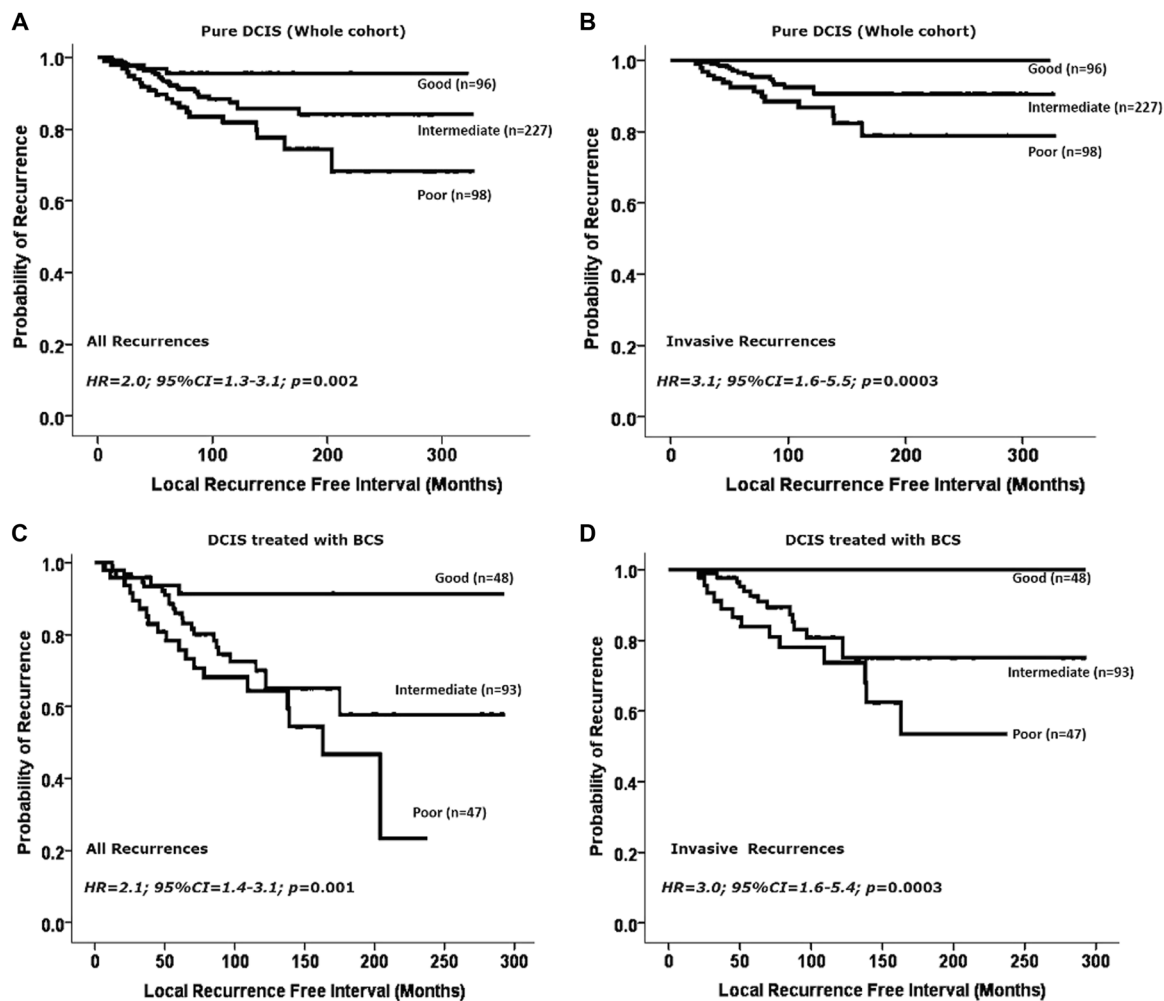

Fig. 4 Kaplan–Meier curves show that the poor collagen prognostic index group is associated with shorter ipsilateral local recurrence-free interval for all recurrences (**a**) and invasive recurrences (**b**) in the

whole series as well as in the breast-conserving surgery-treated group (**c** for all recurrences and **d** for invasive recurrences)

proliferation, migration, invasion, and angiogenesis [36]. A recent genetic study showed that extracellular matrix reorganization and response to cellular stress are key factors in breast cancer progression [37]. Several studies on invasive breast cancer and other types of cancer using second harmonic generation microscopy or multiphoton laser scanning showed that organization of collagen around malignant tissues provides a tumor-associated collagen signature that is associated with tumors behavior and patients' outcome [2, 4, 13]. Given that the role of collagen remodeling in DCIS behavior is relatively understudied, we evaluated the collagen fiber organization surrounding DCIS and its prognostic significance. We have used a novel imaging method, to the best of our knowledge, to assess collagen characteristics in a large cohort of DCIS and have developed a collagen prognostic index to predict the risk of DCIS recurrence and progression.

In this study, we examined the density and arrangement of collagen relative to each other and the boundary of DCIS.

Interestingly, higher collagen prognostic index was associated with features of high-risk DCIS including higher nuclear grade, comedo-type necrosis, hormonal receptor negativity and HER2 positivity, supporting its role in DCIS progression. Additionally, our data showed that collagen prognostic index was higher in DCIS coexisting with invasive breast cancer than pure DCIS. Taken together, collagen re-organization is a potential factor for high-risk DCIS. The poor prognostic value of collagen rearrangement was shown with a shorter local recurrence-free interval in patients with higher levels of collagen prognostic index independently from other clinicopathological factors. These findings were consistent for all recurrent events, either DCIS or invasive breast cancer or when the analysis was confined to invasive recurrences only, which provides more evidence that collagen rearrangement and deposition could play a key role in DCIS progression to invasive disease. Collagen prognostic index could predict the risk of recurrence in non-high-grade DCIS, which is

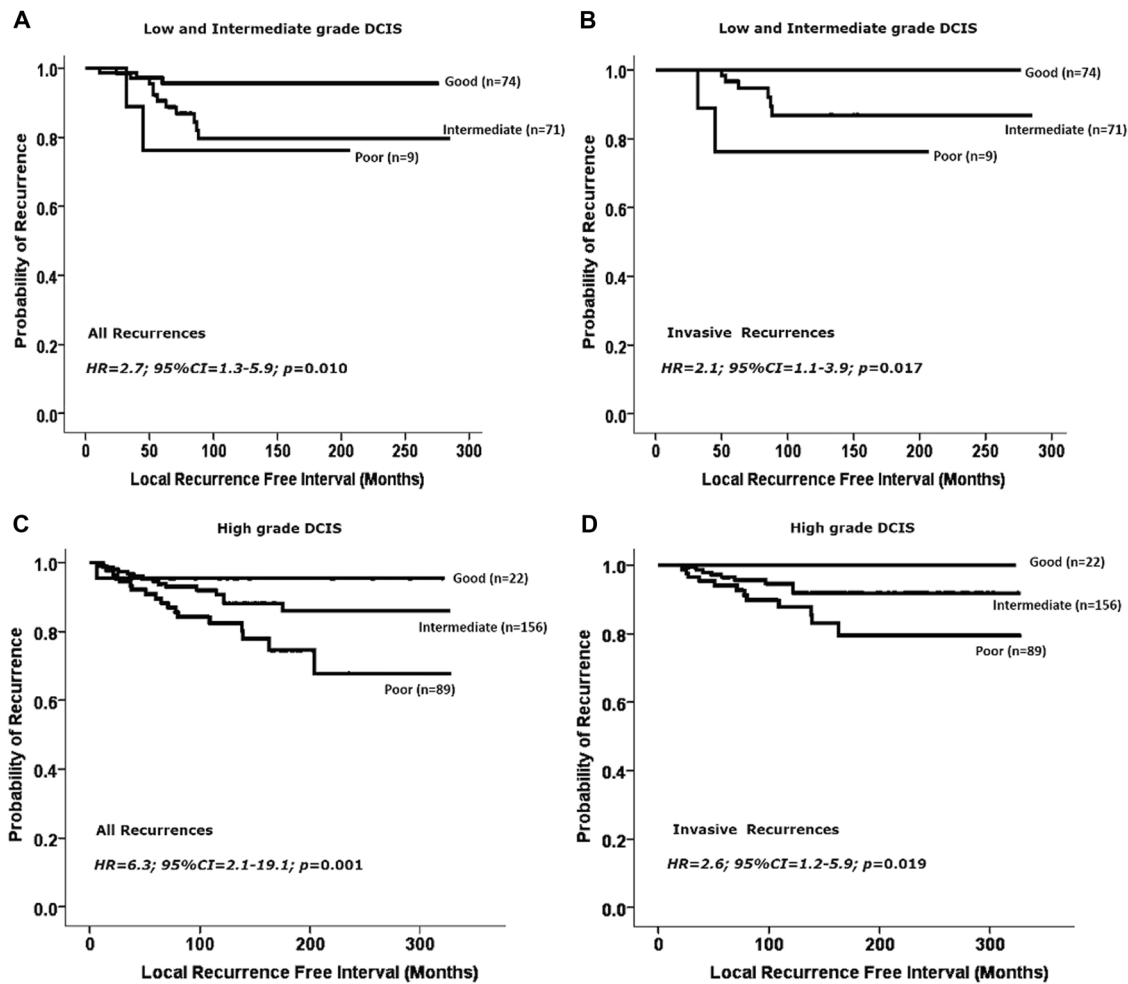

Fig. 5 Kaplan–Meier curves show that the poor collagen prognostic index group is associated with shorter ipsilateral local recurrence-free interval for all recurrences (**a**) and invasive recurrences (**b**) in non-

high-grade DCIS as well as in high-grade DCIS (**c** for all recurrences and **d** for invasive recurrences). DCIS ductal carcinoma in situ

a group at risk of undertreatment due to the lack of accurate predictors of recurrence in this group, although genetic studies showed that the DCIS are the precursors of low-grade invasive breast cancer. Hence, collagen prognostic index could drive the management decision in these patients. The poor prognostic group of non-high-grade DCIS had a 22% risk of invasive recurrence within 10 years, compared to zero invasive recurrences in the good prognostic group.

Although the effect of radiotherapy in the reduction of DCIS recurrence is undeniable [38–41], there is still a considerable percentage of patients treated with breast-conserving surgery and followed by adjuvant radiotherapy that develop disease recurrence. There are no data available for DCIS patients at higher susceptibility for poor response to radiotherapy. Our findings showed that DCIS with a high collagen prognostic index is associated with poor outcome even when radiotherapy was offered. This index could provide a signature for radiotherapy resistance in DCIS. It is

reported that dense stroma is associated with poor response to radiotherapy in cancer treatment [42], which might provide a similar explanation in DCIS. These findings need mechanistic studies for validation.

Although the mechanisms that lead to collagen changes and how these changes affect tumor behavior are not fully understood, several explanations are available. Tumor cells could secrete factors that realign a random collagen matrix into a radially arranged collagen to facilitate local invasion [13]. The role of hypoxia and collagen remodeling proteins such as prolyl-4-hydroxylases alpha subunit 2 and lysyl oxidase are obvious in developing collagen signatures as shown from previous studies and our findings in the current study [10, 43]. As a reciprocal effect, collagen density can affect tumor growth even in tumor harboring scanty stroma. Cells cultured within low-density matrices form well-differentiated acini structures, while colonies that formed within high-density matrices are larger, more proliferative and less organized structures indicating that increasing

DCIS ductal carcinoma in situ

collagen matrix density can directly promote epithelial cell proliferation [4].

Stiffer extracellular matrix due to increased collagen deposition results in high local mechanical loads and higher resistance to cellular contractility [4]. Such changes in the physical microenvironment lead to loss of cellular adhesion, increase tumor cells proliferation and promotes a transformed phenotype. These findings are supported from our results where higher collagen solidity and lower collagen dispersion were associated with a higher proliferation index. Moreover, stromal fibroblasts can regulate epithelial cells in

part through secretion of specific soluble growth factors and chemokines such as tumor growth factor β that has been associated with reactive stroma and fibrosis, while studies indicate that the epidermal growth factors/receptors (i.e. HER2) are important not only in the normal mammary gland but also during tumorigenesis and metastasis [44, 45]. These findings are supported from our results where higher collagen prognostic index was associated with HER2 overexpression and higher proliferation index.

Mechanical forces can induce epithelial mesenchymal transition leading to tumor invasion [2]. With the tumor

mass increasing, stress on extracellular matrix increases correspondingly until reaching a critical point, the biomechanical trigger, which can be sensed by mechanical receptors in both tumor and stromal cells. In turn these cells exert cytoskeletal-dependent traction forces on the extracellular matrix [13, 46, 47]. Eventually, tumor and stromal cells deform as consequences of the altered tissue tension [48, 49], the expanding tumor mass [50], matrix stiffening [51], and increased interstitial pressure due to a leaky vasculature and poor lymphatic drainage, initiating epithelial mesenchymal transition [52]. These deformed cells acquire a more spindle-like fibroblastic morphology, lower adhesive properties, enhanced motility, and invasive behavior. Studies showed that local invasion in stroma-rich areas is due to an intrinsic property of tumor cells arising in a collagen-dense stroma rather than being a simple reflection of increased local collagen that facilitates invasion. Tumor cells isolated from collagen-dense tissues were in fact innately more migratory, indicating that the ease of invasiveness facilitated by certain collagen structures is likely not the sole cause for increased metastasis but that the tumor cells themselves are more invasive [4]. Moreover, aligned collagen provides an adhesive scaffold that support tumor cells in their invasion and migratory process [6, 11–13, 16]. Mechanical forces also activate sites on collagen to recruit monocytes leading to a cascade of innate immuno-inflammatory reactions [2]. Our results showed that dense collagen is associated with denser tumor infiltrating lymphocytes than lesions with scanty and randomly distributed stromal collagen. The underlying biology warrants an investigation, given our previous report that dense tumor infiltrating lymphocytes have poor prognostic significance in DCIS, a reverse phenomenon to that in invasive disease for which the underlying mechanisms are unclear [7].

This study has been carried out on tissue microarray without including full face sections, which might underestimate the role of DCIS heterogeneity. However, all cases in our cohort were histologically reviewed before tissue microarray construction and multiple cores were used for cases with heterogeneous grade or morphological patterns. Also, our cohort did not include patients treated with endocrine therapy.

In conclusion, collagen prognostic index could provide a signature for prediction of DCIS recurrence risk. Collagen deposition and reorganization around DCIS plays a role in tumor progression and recurrence. Collagen features are stable and robust, persisting even when tissues have not been properly fixed, and these features are maintained under various tissue-processing approaches. Thus, picrosirius staining of collagen and subsequent image analysis to assess collagen prognostic index could readily be used in clinical practice and could drive DCIS management

decisions. Additional functional studies to delineate the mechanistic role of collagen reorganization in DCIS behavior are warranted.
