Although guidelines recommend fixed cardiac troponin thresholds for the diagnosis of myocardial infarction, troponin concentrations are influenced by age, sex, comorbidities and time from symptom onset. To improve diagnosis, we developed machine learning models that integrate cardiac troponin concentrations at presentation or on serial testing with clinical features and compute the Collaboration for the Diagnosis and Evaluation of Acute Coronary Syndrome (CoDE-ACS) score (0-100) that corresponds to an individual's probability of myocardial infarction. The models were trained on data from 10,038 patients (48% women), and their performance was externally validated using data from 10,286 patients (35% women) from seven cohorts. CoDE-ACS had excellent discrimination for myocardial infarction (area under curve, 0.953; 95% confidence interval, 0.947-0.958), performed well across subgroups and identified more patients at presentation as low probability of having myocardial infarction than fixed cardiac troponin thresholds (61 versus 27%) with a similar negative predictive value and fewer as high probability of having myocardial infarction (10 versus 16%) with a greater positive predictive value. Patients identified as having a low probability of myocardial infarction had a lower rate of cardiac death than those with intermediate or high probability 30 days (0.1 versus 0.5 and 1.8%) and 1 year (0.3 versus 2.8 and 4.2%; P < 0.001 for both) from patient presentation. CoDE-ACS used as a clinical decision support system has the potential to reduce hospital admissions and have major benefits for patients and health care providers.

High-sensitivity cardiac troponin assays have enabled the adoption of accelerated diagnostic pathways for the assessment of patients with symptoms suggestive of acute myocardial infarction<sup>1-10</sup>. These pathways are now recommended by national and international clinical

practice guidelines, but they have some important limitations<sup>11-13</sup>. First, they use fixed troponin thresholds for all patients, which do not account for age, sex or comorbidities that are known to influence cardiac troponin concentrations<sup>5,14-17</sup>. Second, they are based

A full list of affiliations appears at the end of the paper. e-mail: nick.mills@ed.ac.uk

on specific time points for serial testing, which can be challenging to apply consistently in busy emergency departments<sup>18</sup>. Third, they categorize patients as low, intermediate or high risk of myocardial infarction based on troponin thresholds alone and do not consider other important information, such as the time of symptom onset or findings on the electrocardiogram<sup>19</sup>. Finally, although these pathways perform well to rule out myocardial infarction, identifying those with the condition is more challenging, and the performance of the 99th percentile diagnostic threshold is inconsistent in men and women, in older patients and in those with comorbidities<sup>20–24</sup>. In this study, we hypothesized that machine learning approaches to integrate cardiac troponin as a continuous measure and clinical features known to influence concentrations may provide a more individualized approach to assess probability and improve the diagnosis of myocardial infarction.

In a prespecified analysis of the High-Sensitivity Troponin in the Evaluation of Patients with Suspected Acute Coronary Syndrome (High-STEACS) trial<sup>25</sup>, we evaluated the diagnostic performance of guideline-recommended cardiac troponin thresholds and developed a clinical decision support system called the Collaboration for the Diagnosis and Evaluation of Acute Coronary Syndrome (CoDE-ACS) that uses machine learning models to calculate the probability of myocardial infarction for an individual patient. We then externally validated the diagnostic performance of CoDE-ACS and compared performance with guideline-recommended pathways to demonstrate how it could be used in clinical practice.

#### Results

The derivation cohorts together were composed of 10,038 patients (median age 70 years, 48% women) with possible myocardial infarction presenting to 1 of 10 secondary or tertiary care hospitals in Scotland (Table 1 and Extended Data Fig. 1). The ground truth was determined according to the Fourth Universal Definition of Myocardial Infarction<sup>11</sup> following review of all clinical information and investigations by two clinicians independently, with a third reviewer providing consensus if there was disagreement. The diagnostic outcome was prespecified and included all patients with an adjudicated diagnosis of type 1, 4b or 4c myocardial infarction without ST-segment elevation during the index hospital admission. Models to estimate the probability of myocardial infarction were trained separately in consecutive patients with and without myocardial injury at presentation, defined as a cardiac troponin I concentration above or below the sex-specific 99th percentile upper reference limit on the first measurement. In 6.239 and 3.799 patients with and without myocardial injury at presentation, the final adjudicated diagnosis after serial cardiac troponin measurements was type 1. 4b or 4c myocardial infarction in 3,094 and 132 patients, respectively.

#### Diagnostic performance of cardiac troponin thresholds

In patients without myocardial injury, the negative predictive value of the rule-out threshold of less than 5 ng  $l^{-1}$  at presentation was 99.6 (95% confidence interval (95% Cl), 99.3–99.8) (Supplementary Table 1). The negative predictive value was lower in patients presenting within 3 h of symptom onset (Extended Data Fig. 2). Among patients with myocardial injury at presentation, the positive predictive value of the sex-specific 99th percentile upper reference limit was 49.4 (95% Cl, 48.2–50.7). There was significant heterogeneity in all subgroups, with a lower positive predictive value in those older than 65 years old, in women and in those with ischemic heart disease and impaired renal function (Fig. 1).

#### Training and internal validation of models

An XGBoost model was the best-performing model in patients with and without myocardial injury at presentation and when using the first cardiac troponin measurement or serial measurements (Supplementary Table 2). These XGBoost models were combined within a single clinical decision support system called CoDE-ACS, which computes a score (0–100) corresponding to an individual patient's probability of myocardial infarction (https://decision-support.shinyapps.io/code-acs/). CoDE-ACS models combine cardiac troponin as a continuous measure with age, sex, time from symptom onset, the presence of chest pain, known ischemic heart disease, hyperlipidemia, heart rate, systolic blood pressure, Killip class, myocardial ischemia on the electrocardiogram, renal function and hemoglobin (Extended Data Fig. 3).

In patients without myocardial injury at presentation, a CoDE-ACS score of less than three met our prespecified diagnostic performance criteria with a negative predictive value of 99.5 (99.3–99.8) and sensitivity of 90.2 (84.7–95.0). In those with myocardial injury, a CoDE-ACS score of 61 or more met our prespecified diagnostic performance criteria with a positive predictive value of 80.1 (78.5–81.6) and specificity of 83.4 (82.1–84.7). These scores identifying patients at low and high probability of myocardial infarction performed consistently across subgroups (Extended Data Fig. 4).

When the presentation and first serial measure of cardiac troponin were incorporated within the models, the same scores of less than 3 and 61 or more that identified patients at low and high probability of myocardial infarction at presentation gave a negative predictive value of 99.5 (99.2–99.8) and sensitivity of 95.5 (92.0–98.5) in those without myocardial injury at presentation and a positive predictive value of 82.5 (81.1–83.9) and specificity of 80.1 (78.4–81.6) in those with myocardial injury (Extended Data Fig. 5). The diagnostic performance of these scores in the models incorporating serial measurements was also consistent across patient subgroups.

#### **External validation**

The external validation cohort consisted of 10,286 patients (median age 60 years, 35% women) with possible myocardial infarction pooled from seven prospective cohort studies enrolling patients across six countries (Table 1). In 8,664 and 1,622 patients with and without myocardial injury at presentation, the final adjudicated diagnosis after serial cardiac troponin measurements was myocardial infarction in 1,032 and 267 patients, respectively. Discrimination of the CoDE-ACS models was excellent, with an area under curve of 0.953 (95% CI, 0.947–0.958) at presentation and 0.966 (95% CI, 0.961–0.970) on serial testing. Similarly, calibration was good using presentation cardiac troponin alone and serial measurements (Brier scores of 0.053 and 0.051, respectively) (Fig. 2 and Extended Data Fig. 6).

# CoDE-ACS pathway compared with cardiac troponin thresholds

In 10,286 patients from the external validation cohort, there was a total of 1,299 (13%) with a final diagnosis of myocardial infarction. When a threshold of less than 5 ng l<sup>-1</sup> at presentation was applied to those without myocardial ischemia on the electrocardiogram in whom symptom onset was more than 3 h from testing, the proportion ruled out was 27% (2,819 of 10,286). The negative predictive value and sensitivity were 99.7 (95% CI, 99.5–99.8) and 98.3 (95% CI, 97.8–98.6), respectively. When the sex-specific 99th percentile diagnostic thresholds were applied at presentation, the proportion ruled in was 16% (1,622 of 10,286), with a positive predictive value and specificity of 63.6 (95% CI, 62.7–64.5) and 93.4 (95% CI, 92.9–93.9), respectively. The remaining 57% (5,845 of 10,286) of patients had intermediate cardiac troponin concentrations or required serial testing as they presented early or had an abnormal electrocardiogram.

A CoDE-ACS score of less than three identified 61% (6,265 of 10,286) of patients in the external validation cohort as low probability at presentation, with a negative predictive value of 99.6 (95% Cl, 99.4–99.7) and a sensitivity of 97.9 (95% Cl, 97.6–98.2) (Fig. 3 and Supplementary Tables 3 and 4). A CoDE-ACS score of 61 or greater identified 10% (1,052 of 10,286) of patients at presentation as high probability, with a positive predictive value of 75.5 (95% Cl, 74.6–76.3) and a specificity of 97.1 (95% Cl, 96.8–97.4) (Fig. 3). Both the low- and high-probability scores

Values are median (interquartile range) or *n* (percentage). ACE, angiotensin converting enzyme; ARB, angiotensin receptor blockers; CABG, coronary artery bypass grafting; eGFR, estimated glomerular filtration rate; NA, not applicable; PCI, percutaneous coronary intervention. <sup>a</sup>Two medications from aspirin, clopidogrel, prasugrel or ticagrelor. <sup>b</sup>Includes warfarin or novel oral anticoagulants.

performed well in the validation cohort across all subgroups, although there was some heterogeneity observed by age and sex (Fig. 4 and Extended Data Fig. 7).

There were 2,969 (29%) patients in the validation cohort with a CoDE-ACS score of 3–60 at presentation in whom serial testing would be recommended. When the first serial measure of cardiac troponin at any time point was incorporated, a CoDE-ACS score of less than

3 and 61 or greater identified a further 1,172 (11%) and 490 (5%) patients as low and high probability, respectively. Overall, this resulted in 72% (7,437 of 10,286) of patients being identified as low probability with a negative predictive value of 99.6 (95% CI, 99.4–99.7) and sensitivity of 97.5 (95% CI, 97.2–97.8) and 15% (1,542 of 10,286) of patients being identified as high probability with a positive predictive of 71.3 (95% CI, 70.4–72.1) and specificity of 95.1 (95% CI, 94.6–95.5), respectively

**Fig. 2** | **Diagnostic performance of the CoDE-ACS score in the external validation cohort using the presentation troponin concentration alone. a**, Receiver-operating characteristic curve illustrating the discrimination of the CoDE-ACS for myocardial infarction. **b**, Calibration of the CoDE-ACS score with the observed proportion of patients with myocardial infarction. The dashed line

represents perfect calibration. Each point represents 100 patients. Patients are grouped as low (<3), intermediate (3–60) or high probability ( $\geq$ 61) of myocardial infarction. The darker shaded area represents the 95% CI, while the lighter shaded area represents the 99% CI. AUC, area under curve.

(Fig. 3 and Supplementary Table 3). After two cardiac troponin tests, the probability remained intermediate in 1,342 (13%) patients, but individual CoDE-ACS scores along with diagnostic metrics associated with those scores are provided within the clinical decision support system and could be used to select patients for further inpatient assessment or outpatient follow-up.

In a series of post hoc analyses, the CoDE-ACS pathway was also validated in a cohort from the US, where the prevalence of myocardial

infarction is lower, compared with serial cardiac troponin measurements with relative change criteria and evaluated separately in women and men. In a US cohort of 1,571 patients in whom 64 (4%) had a diagnosis of myocardial infarction, the pathway identified 49% (73 of 1,571) of patients as low probability at presentation with a similar negative predictive value of 99.9 (95% Cl, 99.5–100) and a sensitivity of 98.4 (95% Cl, 97.7–98.9) and 2% (39 of 1,571) of patients as high probability with a lower positive predictive value of 61.5 (95% Cl, 59.1–63.9) but a similar

**Fig. 3** | **External validation of the performance of the CoDE-ACS pathway in 10,286 patients with possible myocardial infarction.** Diagnostic performance of CoDE-ACS models in 10,286 patients from seven international cohorts. Sensitivity, negative predictive value (NPV), specificity and positive predictive value (PPV) with 95% CIs of the CoDE-ACS scores were used to identify patients as low probability (<3) or high probability ( $\geq$ 61) of myocardial infarction at presentation and after serial troponin testing if required.

specificity of 99.0 (95% CI, 98.4-99.4) compared with the external validation cohort (Supplementary Table 5). CoDE-ACS was compared with serial cardiac troponin measurements using a relative increase of 20% where the initial value is above the 99th percentile and a relative increase of 50% when it is below the 99th percentile. In the external validation cohort, a CoDE-ACS score of 61 or greater identified more patients as high probability compared with these criteria (15% (1,542 of 10,286) versus 10% (995 of 10,286)) with a higher positive predictive value (71.3 (95% CI. 70.4-72.1) versus 67.4 (95% CI. 66.5-68.3)) and similar specificity (Supplementary Table 6). The CoDE-ACS pathway was evaluated in 3,629 women and 6,657 men from the external validation cohort separately (Extended Data Fig. 8). Performance of the low-probability score and effectiveness were similar in women and men, but the positive predictive value of the high-probability score was lower in women at 67.5 (95% CI, 65.9-69.0) compared with 78.5 (95% CI, 77.5–79.4) in men. Despite differences in disease prevalence between the studies used for external validation, CoDE-ACS performed well across different health care settings (Extended Data Fig. 9). A sensitivity analysis was performed in the external validation cohort, reporting the performance of the CoDE-ACS pathway for a broader diagnostic outcome of type 1, 4b, or 4c or type 2 myocardial infarction (Supplementary Table 7).

#### CoDE-ACS pathway compared with other pathways

In our external validation cohort, 5,634 patients had cardiac troponin measurements at presentation and 1 h to enable a comparison of the CoDE-ACS and 0/1-h pathways, with 774 (14%) having a final diagnosis of myocardial infarction (Supplementary Table 8). CoDE-ACS identified twice as many patients as low probability as the 0/1-h pathway at presentation (57 versus 27%) for a similar negative predictive value (99.7 (95% CI, 99.5–99.8) versus 99.9 (95% CI, 99.8–100)) (Extended Data Fig. 10). CoDE-ACS identified a similar proportion of patients as high probability as the 0/1-h pathway at presentation (12 versus 13%) for a higher positive predictive value (67.8 (95% CI, 66.6–69.0) versus 62.3 (95% CI, 61.0–63.5)). When serial measures at 0 and 1 h were incorporated, the CoDE-ACS pathway identified fewer patients as intermediate probability than the 0/1-h pathway (14 versus 29%).

In our external validation cohort, 2,271 patients had the required clinical features and cardiac troponin measurements at presentation and 3 h to enable a comparison of the CoDE-ACS and History, Electrocardiogram (ECG), Age, Risk Factors, and Troponin (HEART) pathways, with 360 (16%) having a final diagnosis of myocardial infarction (Supplementary Table 9). The HEART pathway does not rule out any patients at presentation, whereas CoDE-ACS identified 51% (1,169 of 2,271) as low probability with a negative predictive value of 99.6 (95% CI, 99.2–99.8). At 3 h, CoDE-ACS identified four times as many patients at low probability as the HEART pathway (66 versus 16%) for a similar negative predictive value (99.7 (95% CI, 99.3–99.8) versus 100 (95% CI, 99.8–100)). The positive predictive value of the high-risk criteria in the HEART pathway was significantly lower than the high-probability score from the CoDE-ACS pathway (19.0 (95% CI, 17.4–20.6) versus 69.7 (95% CI, 67.7–71.5)).

Pathways that incorporate machine learning models are more flexible than those using fixed cardiac troponin thresholds or risk scores, allowing health care systems to apply different criteria to define low and high probability of myocardial infarction. For example, a pathway incorporating a lower CoDE-ACS score of two will identify fewer patients as low probability of myocardial infarction at presentation than one using a score of three (50 versus 61%) for a higher negative predictive value (99.7 (95% CI, 99.6–99.8) versus 99.6 (95% CI, 99.4–99.7)) and sensitivity (98.8 (95% CI, 98.6–99.0) versus 97.9 (95% CI, 97.6–98.2)) (Supplementary Table 10).

#### Outcomes stratified by the CoDE-ACS score

At 1 year, there were 144 (1.4%) deaths from a cardiac cause and 317 (3.1%) deaths of any cause in the external validation cohort. Compared with

Fig. 4 | Diagnostic performance of the CoDE-ACS score in the external validation cohort for identifying patients as having a low or high probability of myocardial infarction across patient subgroups. Data are presented as a central estimate with 95% CIs based on the Clopper–Pearson method. **a**, Negative predictive

value of the low-probability CoDE-ACS score using the presentation troponin concentration alone across patient subgroups. **b**, Positive predictive value of the high-probability CoDE-ACS score using the presentation troponin concentration alone across patient subgroups. eGFR, estimated glomerular filtration rate.

Fig. 5 | Cumulative incidence of cardiac death and all-cause mortality as stratified by the CoDE-ACS score at presentation in the external validation cohort. a,b, Data for cardiac death (a) and all-cause mortality (b).

patients identified by CoDE-ACS at presentation as intermediate or high probability, those who were low probability of myocardial infarction had a lower rate of cardiac death and all-cause death at 30 days (cardiac death: 0.1 versus 0.5 and 1.8%; all-cause death: 0.1 versus 0.9 and 2.0%, respectively) and at 1 year (cardiac death: 0.3 versus 2.8 and 4.2%; all-cause death: 1.1 versus 6.1 and 6.7%, respectively; log-rank test P < 0.001) (Fig. 5).

#### Discussion

In patients presenting with possible acute myocardial infarction, we developed and validated the CoDE-ACS clinical decision support system using machine learning with single or serial high-sensitivity cardiac troponin measurements to inform the probability of acute myocardial infarction.

Compared with guideline-recommended pathways using cardiac troponin thresholds and risk scores, CoDE-ACS identified twice as many patients as low probability of myocardial infarction at presentation with a similar negative predictive value and fewer patients as high probability with an improved positive predictive value. Unlike recommended cardiac troponin thresholds. CoDE-ACS scores performed well in subgroups, including men and women, older persons, those with renal impairment or those who present early following the onset of symptoms. We validated performance across multiple health care systems, where the prevalence of myocardial infarction varied from 4 to 16%, and propose a pathway that identifies up to two thirds of patients as low probability of myocardial infarction with a single troponin test and improves the recognition of those with elevated cardiac troponin concentrations who have acute myocardial infarction. While our models were trained to estimate the probability of myocardial infarction during the index hospital admission, patients who were identified as low probability of myocardial infarction were also at low risk of death following discharge, with fewer than 1 in 300 having a cardiac death at 1 year. If adopted in practice, the CoDE-ACS clinical decision support system could reduce time spent in emergency departments, prevent unnecessary hospital admission in patients unlikely to have myocardial infarction and at low risk of cardiac death, and improve the recognition and treatment of those with myocardial infarction rather than myocardial injury, with benefits for both patients and health care providers.

Our study has directly benefited from a substantial body of prior research describing the relationship between cardiac troponin and coronary heart disease, which has transformed the assessment of patients

Nature Medicine | Volume 29 | May 2023 | 1201-1210

with possible myocardial infarction<sup>26-33</sup>. In particular, approaches harnessing high-sensitivity assays that can quantify cardiac troponin at concentrations well below the diagnostic threshold for myocardial infarction and pathways incorporating risk scores<sup>34</sup> have been instrumental in improving care<sup>1-5,10</sup>. The use of statistical modeling to guide clinical decisions represents a logical progression of this field and has several important advantages over prior approaches using fixed troponin thresholds or risk scores alone. First, cardiac troponin is known to be influenced by age, sex and renal function<sup>21-24</sup>. Our findings from an unselected cohort of consecutive patients demonstrate marked heterogeneity in the performance of the diagnostic threshold across these groups that was minimized when a model incorporating these features was applied. Second, patients with different symptoms, comorbidities and risk factors have a different pretest probability of having nonischemic myocardial injury or myocardial infarction<sup>35–37</sup>. Incorporating these features into the CoDE-ACS models rather than considering them in isolation as applied in the HEART pathway significantly improved the positive predictive value of an elevated cardiac troponin for myocardial infarction compared with using the same fixed troponin threshold in all patients irrespective of pretest probability. Third, current national and international guidelines recommend serial cardiac troponin measurements in all patients who present within 3 h of symptom onset<sup>11-13</sup>, as it takes time following an episode of myocardial ischemia for cardiac troponin to increase above the thresholds recommended to rule out myocardial infarction<sup>38,39</sup>. CoDE-ACS, by incorporating time from symptom onset, enables early presenters to be ruled out using a single test. Finally, current pathways recommend fixed time points for serial measurements in those who have intermediate cardiac troponin concentrations, which can be challenging to implement in routine practice and may unnecessarily increase the duration of stay. Previous studies have shown that between one in five and one in three patients do not undergo cardiac troponin testing in accordance with pathway recommendations<sup>10,40</sup>. In the 29% of patients not identified as low or high probability using a single cardiac troponin measurement, CoDE-ACS, by incorporating information on the time of testing, permits a second measurement to be incorporated at a flexible time point. The CoDE-ACS pathway incorporating a serial measurement at a flexible time point reduced the proportion of patients requiring further observation and testing twofold and will reduce the potential for harm due to nonadherence with the timing of the serial measurement that is inherent to current diagnostic pathways.

The CoDE-ACS clinical decision support system was influenced by pioneering early studies<sup>41</sup> and represents a substantial advance on our previous work<sup>42</sup>. The Troponin-Only Manchester Acute Coronary Syndromes score combines cardiac troponin T concentrations at presentation with other clinical observations using logistic regression to identify a third of patients with suspected acute coronary syndrome as low risk of major adverse cardiac events<sup>41</sup>. The myocardial-ischemicinjury index (MI<sup>3</sup>) uses gradient boosting to compute a probability of myocardial infarction but has several limitations. First, while CoDE-ACS ruled in or ruled out myocardial infarction in 71% of patients with a single cardiac troponin test, MI<sup>3</sup> requires two measurements in all patients to estimate probability. In practice, this would significantly limit the effectiveness of MI<sup>3</sup> given that accelerated diagnostic pathways in use today enable decisions based on a single cardiac troponin measurement and have been shown to be safe and to prevent unnecessary admissions<sup>8,10,40</sup>. Second, the MI<sup>3</sup> score was calculated using only age, sex and cardiac troponin concentrations. Although the use of a limited number of variables is laudable for its simplicity, by not including other important features that influence cardiac troponin, the positive predictive value and specificity were lower in patients with comorbidities<sup>43</sup>. Finally, MI<sup>3</sup> was developed in a small cohort of selected patients, and when we performed a validation in unselected consecutive patients, we observed that calibration was poor, particularly for those at intermediate probability<sup>43</sup>. CoDE-ACS overcomes these limitations by estimating probability using a single cardiac troponin measurement, including other features that influence cardiac troponin concentrations and pretest probability, and by training the model in a large unselected patient population.

The advantage of using machine learning models within a clinical decision support system over fixed cardiac troponin thresholds to generate a probability of myocardial infarction and the diagnostic metrics associated with this probability is that health care systems can apply a decision support system more flexibly. For example, in a health care setting that is more conservative, a lower CoDE-ACS score to identify patients as being at very low probability of myocardial infarction with a negative predictive value of 99.8 and false-negative rate of 1 in 500 could be applied to guide discharge in 50% of patients with a single test. Alternatively, in health care settings where capacity in the emergency department is limited, a lower CoDE-ACS score to identify those as high probability could be applied to reduce the proportion of patients considered of intermediate probability who require observation and serial testing within the department. Our clinical decision support system provides users with the option to select the diagnostic parameters and therefore, the CoDE-ACS score to define low and high probability in order to create a pathway that is optimal for patient flow according to local clinical priorities (https://decision-support.shinyapps.io/code-acs/). In the future, it may be possible to integrate CoDE-ACS with other machine learning approaches using the 12-lead electrocardiogram to further refine performance and reduce the proportion of patients requiring observation<sup>44</sup>. Likewise, the inclusion of findings from other investigations could help our models learn to differentiate between type 1 and type 2 myocardial infarction.

While CoDE-ACS may enable a more flexible approach to the interpretation of cardiac troponin results and therefore, the correct triage of patients in practice, we continue to advocate the use of a sex-specific 99th percentile as the diagnostic threshold for myocardial infarction. Indeed, this threshold was used to adjudicate all cases of myocardial infarction in our derivation and validation cohorts<sup>25,45-49</sup>. However, we recognize the limitations of applying a fixed threshold derived from a reference range population to individual patients who may not be represented in these cohorts. Despite incorporating sex into the CoDE-ACS models, the positive predictive value of the high-probability score was lower in women than men. This may represent true biological differences in the probability of myocardial infarction in women and men or unintended selection bias when enrolling patients into the external validation cohorts. Ultimately, myocardial infarction is a clinical diagnosis that requires judgment to interpret the presenting symptoms and signs and findings from troponin testing and cardiac imaging. We anticipate that use of machine learning models within the CoDE-ACS clinical decision support system will augment rather than replace this clinical judgment and minimize inequalities in care.

Several limitations merit consideration. First, the CoDE-ACS models have been trained and validated using a high-sensitivity cardiac troponin I assay from a single manufacturer. Given that cardiac troponin assays are not standardized across different manufacturers, CoDE-ACS will need to be retrained and validated for other assays. Second, confirmation bias may in part explain the excellent performance of the CoDE-ACS models as they incorporate features that are integral to the diagnosis of myocardial infarction. This was minimized as the ground truth was defined prior to the development of the CoDE-ACS model and does not make CoDE-ACS any less useful as an objective measure of probability in practice. Third, there were important differences in the characteristics of patients enrolled in our derivation and validation cohorts, which likely reflect differences in study inclusion and exclusion criteria, disease prevalence and health care system factors. Despite these differences, CoDE-ACS performed well in different health care settings. However, the enrollment of consented patients rather than unselected patients may have introduced some selection bias, with overrepresentation of younger male patients responsible for the less consistent performance of CoDE-ACS across some subgroups in the validation cohort. Despite this heterogeneity, the false-negative rate was less than 1 in 100 across subgroups, even in those with increased pretest probability of myocardial infarction. We acknowledge that in high-risk subgroups, such as those older than 65 years old or with prior ischemic heart disease or renal impairment, additional prospective validation would be useful. No decision support system or pathway should be used without consideration of pretest probability and clinical judgment. In our application, the predictive values are reported alongside the score for individual patients, so clinicians can use this information to guide care. Fourth, although our evaluation included participants from across seven countries, the majority were White, and therefore, we were not able to evaluate whether diagnostic performance was consistent across different ethnic groups. Finally, CoDE-ACS was validated in cohorts that had completed enrollment, and care was not guided by our clinical decision support system. Prospective validation and an evaluation of the impact of providing diagnostic probabilities and decision support on management following implementation of CoDE-ACS into practice are warranted.

In conclusion, we have developed a clinical decision support system using machine learning with single or serial high-sensitivity cardiac troponin measurements to inform the probability of acute myocardial infarction. CoDE-ACS was superior to pathways that use fixed cardiac troponin thresholds or risk scores and performed consistently across different health care systems and patient subgroups. We propose a care pathway that identifies more patients as low probability of myocardial infarction with a single cardiac troponin test and improves the recognition of those with myocardial infarction compared with the current standard of care. If adopted in practice, CoDE-ACS could reduce time spent in emergency departments, prevent unnecessary hospital admissions and improve the early treatment of myocardial infarction, with benefits for both patients and health care providers.

#### Methods

#### **Study population**

The High-STEACS trial population was used for the derivation of the CoDE-ACS models. As previously described, High-STEACS was a stepped-wedged cluster-randomized, controlled trial to evaluate the implementation of a high-sensitivity cardiac troponin I assay in consecutive patients with suspected acute coronary syndrome presenting to 10 secondary and tertiary hospitals in Scotland between 10 June 2013 and 3 March 2016 (ref. 25).

Patients were included in this prespecified secondary analysis (Supplementary Note 1) based on the following criteria: (1) age  $\geq$ 18 years old, (2) presentation with suspected acute coronary syndrome, (3) cardiac troponin measured using the ARCHITECT<sub>STAT</sub> high-sensitivity cardiac troponin I assay (Abbott Laboratories) and (4) availability of electrocardiographic and physiological data for diagnostic adjudication. Patients with a diagnosis of ST-segment elevation myocardial infarction were excluded given they undergo coronary revascularization directly without troponin testing in the emergency department (Extended Data Fig. 1).

#### Adjudication of the ground truth and outcomes

The model was trained to identify patients with an adjudicated diagnosis of type 1, type 4b or type 4c myocardial infarction during the index hospital admission. The ground truth was adjudicated according to the Fourth Universal Definition of Myocardial Infarction by two clinicians independently, with a third reviewer providing consensus if there was disagreement<sup>11,25,50</sup>. All diagnoses were adjudicated where there was evidence of myocardial injury at presentation or on serial testing defined as any high-sensitivity cardiac troponin I concentration above the sex-specific 99th percentile. Type 1 myocardial infarction was defined as myocardial necrosis (any high-sensitivity cardiac troponin I concentration above the 99th percentile with a rise and/or fall in concentration where serial testing was performed) in the context of a presentation with possible myocardial infarction due to either symptoms or signs of myocardial ischemia on the electrocardiogram. Patients with symptoms or signs of myocardial ischemia due to increased oxygen demand or decreased supply (for example, tachyarrhythmia, hypotension or anemia) secondary to an alternative condition or a coronary mechanism other than atherothrombosis and myocardial necrosis were defined as having type 2 myocardial infarction. Types 4b and 4c myocardial infarction were defined where myocardial ischemia and myocardial necrosis were associated with stent thrombosis or restenosis, respectively, on coronary angiography. Regional and national registries were used to follow patients for 1 year. The cause of death was adjudicated by investigators masked to troponin concentrations during the index presentation.

## Performance of guideline-recommended cardiac troponin thresholds

We evaluated the diagnostic performance and proportion of patients identified by guideline-recommended cardiac troponin thresholds to rule out (5 ng  $l^{-1}$ ) and rule in (99th percentile of 16 ng  $l^{-1}$  (women) and 34 ng  $l^{-1}$  (men)) myocardial infarction<sup>21</sup>. These were evaluated in the overall population and in prespecified subgroups by age, sex, time from symptom onset to troponin measurement, renal impairment, prior ischemic heart disease, diabetes mellitus, cerebrovascular disease and ischemia on the electrocardiogram.

#### Feature selection and processing

We used high-sensitivity cardiac troponin I concentrations as a continuous measure. We selected 12 objective clinical variables known to be associated with cardiac troponin concentration and pretest probability of myocardial infarction or to aid in the discrimination of myocardial injury from infarction that were found to have the highest relative importance in our model training phase. These were age, sex, the number of hours from symptom onset to cardiac troponin measurement, chest pain, known ischemic heart disease, hyperlipidemia, heart rate, systolic blood pressure, Killip class, evidence of myocardial ischemia on the electrocardiogram, renal function (estimated glomerular filtration rate calculated using the Chronic Kidney Disease Epidemiology Collaboration formula)<sup>51</sup> and hemoglobin. To maximize the clinical utility of our models, we first developed models using the cardiac troponin concentration at presentation alone. We subsequently developed models to include a second cardiac troponin concentration measured at an early and flexible time point.

#### Model development, selection and external validation

We first developed and evaluated models using four statistical methods-logistic regression, naïve Bayes, random forest and extreme gradient boosting (XGBoost)<sup>52-54</sup>. XGBoost is a supervised machine learning technique initially proposed by Chen and Guestrin<sup>52</sup>. In brief, gradient boosting employs an ensemble technique to iteratively improve model accuracy for regression and classification problems. This ensemble-based algorithm is achieved by creating sequential models using decision trees as learners, where subsequent models attempt to correct errors of the preceding models<sup>53,54</sup>. In the boosting method, individuals who were misclassified by the previous model are assigned a higher weight to increase their chance of being selected in subsequent models. Each model is subsequently fitted in a stepwise fashion to minimize loss function, such as absolute error or squared error (the amount that predicted values differ from the true values). XGBoost refers to the reengineering of gradient boosting to significantly improve the speed of the algorithm by pushing the limits of computational resources. The output of the XGBoost model is a probability that is computed by performing an inverse logit transformation of the sum of the weights of the terminal nodes of the trained model.

The mathematical formula for the gradient boosting model can be described as

$$\hat{y}_i = \sum_{k=1}^{K} f_k \left( \mathbf{x}_i \right), f_k \in F,$$
(1)

where *f* is a function that maps each variable vector  $\mathbf{x}_i (\mathbf{x}_i = \{\mathbf{x}_i, \mathbf{x}_2, ..., \mathbf{x}_n\}, i = 1, 2, N)$  to the outcome  $y_i$ , *K* is the number of Classification and Regression Trees (k = 1, 2, N) and *F* is the space of function containing all Classification and Regression Trees<sup>55</sup>.

XGBoost optimizes an objective function of the form

$$Obj = \sum_{i=1}^{N} l(y_i, \hat{y}_i) + \sum_{k=1}^{K} \Omega(f_k)$$
(2)

where the first term is a loss function l, which evaluates how well the model fits the data by measuring the difference between the prediction  $\hat{y}_i$  and the outcome  $y_i$ . The second term, the regularization term, is used by XGBoost to avoid overfitting by penalizing the complexity of the model. Furthermore, to improve and fully leverage the advantages of XGBoost, we tuned the hyperparameters of the algorithm defined below through a grid search strategy using 10-fold crossvalidation (Supplementary Table 11).

Given that the features that inform diagnosis differ for ruling in and ruling out myocardial infarction, we developed separate models for those with and without myocardial injury at presentation. Here, myocardial injury was defined as a cardiac troponin I concentration above the sex-specific 99th percentile upper reference limit (16 ng l<sup>-1</sup> in women and 34 ng l<sup>-1</sup> in men) on the first measurement<sup>14,21</sup>. Furthermore, given that practice guidelines recommend diagnostic pathways that use a single measure of cardiac troponin to rule in or rule out myocardial infarction, we also trained these models separately using the first cardiac troponin measurement at a flexible time point, resulting in four separate models for each method. For all models in the derivation cohort, we multiply imputed 10 datasets to account for missing data<sup>56</sup> and performed 10 iterations of 10-fold crossvalidation to compute a score (0–100) that corresponded to an individual patient's probability of having myocardial infarction.

We then identified the scores that would classify the highest proportion of patients as high or low probability at prespecified performance criteria for rule in (80% positive predictive value and 80% specificity) myocardial infarction in those with myocardial injury and to rule out (99.5% negative predictive value and 90% sensitivity) myocardial infarction in those without myocardial injury. These criteria were based on prior analysis and an international survey of acceptable risk by physicians<sup>14,42,57</sup>. It is important to highlight that these performance criteria are for the evaluation of scores separately in patients with and without myocardial injury at presentation. When these scores are applied to all patients with possible myocardial infarction, higher sensitivity and specificity would be anticipated and required in practice.

The model with the best discrimination in those without myocardial injury at presentation that identified the largest proportion of patients as low probability according to our prespecified performance criteria was selected and integrated into our CoDE-ACS clinical decision support system (https://decision-support.shinyapps.io/code-acs/).

We externally validated CoDE-ACS in the Advantageous Predictors of Acute Coronary Syndromes Evaluation (APACE), the Improved Assessment of Chest Pain Trial (IMPACT), the 2-Hour Accelerated Diagnostic Protocol to Assess Patients with Chest Pain Symptoms Using Contemporary Troponins as the Only Biomarker (ADAPT), the Emergency Department Assessment of Chest Pain Score (EDACS), the Signal Peptide in Acute Coronary Events (SPACE) and the Use of Abbott High Sensitivity Troponin I Assay in Acute Coronary Syndromes (UTROPIA) cohorts from Switzerland, Spain, Poland, Czech Republic, Australia, New Zealand and the US<sup>45-4958</sup>. All analyses were performed in R v.4.1.2.

# Description of the cohort studies pooled for external validation

APACE. Study design and population. APACE was a prospective international multicenter study with 12 centers in five countries aiming to advance the early diagnosis of myocardial infarction (Clinical Trials. gov registry number NCT00470587). From the 8,267 adult patients  $(\geq 18 \text{ years})$  presenting to the emergency department with symptoms suggestive of myocardial infarction, 5.995 were included in the external validation dataset. Cardiac troponin samples from enrollment and on serial testing at 1, 2 or 3 h depending on availability were used for validation of the CoDE-ACS models. While enrollment was independent of renal function, we excluded patients with terminal kidney failure on chronic dialysis. The study was carried out according to the principles of the Declaration of Helsinki and approved by the local ethics committees. Written informed consent was obtained from all patients. For this analysis, patients with an ST-segment elevation myocardial infarction, patients with missing high-sensitivity cardiac troponin I concentrations at presentation and patients in whom the diagnosis remained unknown even after final adjudication with at least one elevated cardiac troponin concentration, thereby possibly indicating myocardial infarction, were excluded.

Adjudication and follow-up. Myocardial infarction was defined and cardiac troponin concentrations were interpreted as recommended in current guidelines<sup>59-61</sup>. In brief, myocardial infarction was diagnosed when there was evidence of myocardial injury with a clinically significant rise and/or fall in a clinical setting consistent with myocardial ischemia. Patients with myocardial infarction were further classified into type 1 (primary coronary events) and type 2 (ischemia due to increased demand or decreased supply: for example, tachyarrhythmia or hypertensive urgency)<sup>12,59</sup>. All other patients were classified as unstable angina, noncardiac chest pain, cardiac but noncoronary disease

(for example, tachyarrhythmia or myopericarditis) or symptoms of unknown origin with normal concentrations of cardiac troponin.

The adjudication of final diagnoses was performed centrally in the core laboratory (University Hospital Basel) for all patients using the Abbott ARCHITECT high-sensitivity cardiac troponin I assay (Abbott Laboratories). More specifically, two independent cardiologists not directly involved in patient care reviewed all available medical records (including patient history, physical examination, results of laboratory testing (including cardiac troponin concentrations), radiological tests, electrocardiography, echocardiography, cardiac exercise test, lesion severity and morphology in coronary angiography, and the discharge summary) pertaining to the patient from the time of emergency department presentation to 90-day follow-up. In situations of diagnostic disagreement, cases were reviewed and adjudicated in conjunction with a third cardiologist. Sex-specific 99th percentile upper reference limits of the high-sensitivity cardiac troponin I assay (16 ng l<sup>-1</sup> in women, 34 ng l<sup>-1</sup> in men) were used to define myocardial injury. Absolute changes in cardiac troponin were used to determine clinically significant changes<sup>62-66</sup>. Based on studies of the biological variation of cardiac troponin<sup>67,68</sup> as well as on data from previous chest pain cohort studies<sup>62,69</sup>, a clinically significant absolute change was defined as a rise or fall of at least 10 ng l<sup>-1</sup> within 6 h or in an assumption of linearity, as an absolute change of 6 ng l<sup>-1</sup> within 3 h. Patients were contacted 3 and 12 months after discharge by telephone calls or in written form. Information regarding death during follow-up was furthermore obtained from the patient's hospital notes, the family physician's records and the national registry on mortality.

IMPACT. Study design and population. IMPACT was an intervention trial on adult patients in the emergency department with potential acute coronary syndrome (ACTRN12611000206921)<sup>47</sup>. In total, 1,366 patients were recruited prospectively between February 2011 and March 2014, while 1,086 were included in the validation dataset. Cardiac troponin samples from enrollment and at 2 h were used for validation of the CoDE-ACS models. The study was approved by the Royal Brisbane and Women's Hospital Human Research and Ethics Committee (HREC/10/QRBW/403). Informed written consent was obtained from all participants. Recruitment occurred between 0800 and 1700 and included patients aged  $\geq$ 18 years with at least 5 min of symptoms suggestive of and planned testing for acute coronary syndrome. Research staff identified eligible patients. Patients were excluded if they had a clear nonacute coronary syndrome cause for their symptoms, they were unwilling or unable to provide informed consent (for example, language barrier), staff considered that recruitment was inappropriate (for example, terminal illness), they were transferred from another hospital, they were pregnant, they were recruited to the study within the previous 30 days or they were unable or unwilling to be contacted after discharge.

Risk stratification occurred per the IMPACT protocol. Initial troponin and electrocardiographic testing was performed on presentation. High-risk patients were treated according to the 2006 National Heart Foundation/Cardiac Society of Australia and New Zealand guidelines. Low- and intermediate-risk patients were assessed using an accelerated investigation strategy, with repeat troponin testing 2 h after the first test. Routine inpatient stress testing was recommended only for intermediate-risk patients. Low-risk patients were discharged after normal 0- and 2-h biomarkers, with correspondence to their general practitioner stating that additional objective testing was not indicated. Cardiac troponin was measured by the Beckman Coulter second-generation AccuTnI assay (Beckman Coulter) to guide clinical practice and in stored material using the Abbott ARCHITECT high-sensitivity cardiac troponin I assay (Abbott Laboratories). This clinical assay is a sensitive troponin assay with a coefficient of variation of 14% at the 99th percentile value of 0.04  $\mu$ g l<sup>-1</sup> and a 10% coefficient of variation of 0.06  $\mu$ g l<sup>-1</sup>. Values of >0.04  $\mu$ g l<sup>-1</sup> were considered elevated.

Blood samples were taken on presentation and 2 h later for low- and intermediate-risk patients and at 0 and 6 h for high-risk patients. All available troponin results were used for clinical decision-making.

Adjudication and follow-up. Telephone follow-up occurred 30 days after presentation by research nurses. All information was verified through medical record databases and cardiac investigation results. Outcomes were adjudicated independently by local cardiologists using predefined standardized reporting definitions, with access to the clinical record, electrocardiogram, cardiac troponin measurements and all subsequent investigations from standard care. A second cardiologist conducted a blind review of all acute coronary syndromes and 10% of nonacute coronary syndrome cases. In cases of disagreement between the two adjudicators, end points were agreed on by consensus. Myocardial infarction was defined according to international guidelines and based on evidence of myocardial necrosis and ischemia. Patients with acute myocardial infarction were further subdivided into acute myocardial infarction type 1 (primary coronary events) and acute myocardial infarction type 2 (ischemia due to increased demand or decreased supply: for example, tachyarrhythmias or hypertensive crisis). Myocardial necrosis was defined as a 20% increase or decrease in cardiac troponin concentration with at least one value above the 99th percentile of the normal reference range. Evidence of myocardial ischemia included the electrocardiogram or cardiac imaging.

ADAPT-BSN (Brisbane). Study design and population. The ADAPT-BSN trial was a prospective observational validation study designed to assess a predefined accelerated diagnostic pathway that consisted of the TIMI (thrombolysis in myocardial infarction) score risk assessment, electrocardiogram (ECG), and 0- and 2-h central laboratory contemporary cardiac troponin I as the only biomarker. The original study population was from both Brisbane, Australia and Christchurch, New Zealand<sup>48</sup>. From November 2008 to February 2011, a total of 978 unselected patients presenting to the emergency department of the Royal Brisbane and Women's Hospital with symptoms of possible acute myocardial infarction were recruited, while 797 patients were included in the validation dataset. Cardiac troponin samples from enrollment and 2 h were used for validation of the CoDE-ACS models. Criteria for enrollment included age  $\geq 18$  years of age with at least 5 min of symptoms where the attending physician planned to perform serial cardiac troponin tests. Patients were excluded for any of the following: a clear cause other than acute coronary syndrome for the symptoms (for example, examination findings of pneumonia), inability to provide informed consent, staff considered recruitment to be inappropriate (for example, receiving palliative treatment), transfer from another hospital, pregnancy, previous enrollment or inability to be contacted after discharge. Perceived high risk was not used as an exclusion criterion. Written informed consent was obtained from all patients. Patients were managed according to local hospital protocols, including clinical history, physical examination, 12-lead ECG, continuous ECG monitoring, pulse oximetry, standard blood tests and chest radiography. Clinical blood draws for local cardiac troponin measurement were performed at presentation and then, 6-12 h afterward. Management of patients was at the discretion of the attending physician.

Adjudication and follow-up. Final diagnoses were adjudicated by independent cardiologists not directly involved in patient care. Adjudication was based on all available medical records (including patient history, physical examination, all laboratory testing (including cardiac troponin levels), radiological testing, electrocardiography, echocardiography, cardiac exercise test, lesion severity and morphology in coronary angiography, and the discharge summary) pertaining to the patient from the time of emergency department presentation to 30-day follow-up. Myocardial infarction was diagnosed when there was evidence of myocardial necrosis with a clinically significant rise and/or fall in a clinical setting consistent with myocardial ischemia. Patients with acute myocardial infarction were further subdivided into type 1 myocardial infarction (primary coronary events) and type 2 myocardial infarction (ischemia due to increased demand or decreased supply). After discharge, patients were contacted after 6 weeks and 12 months (Brisbane) by telephone calls or in written form. Information regarding death was furthermore obtained from the patients' hospital notes, the family physician's records and the national registry on mortality.

**ADAPT-CH (Christchurch). Study design and population.** The ADAPT-CH study was prospectively performed in accordance with the ADAPT-BSN study (see above). From the 1,125 patients recruited between February 2011 and March 2014, 1,000 were included in the validation dataset. Cardiac troponin samples from enrollment and 2 h were used for validation of CoDE-ACS models. It aimed to compare the effectiveness of a rapid diagnostic pathway with a standard care diagnostic pathway for the assessment of patients with possible cardiac chest pain in a usual clinical practice setting. Patients in the emergency department, where the attending physician was investigating for possible acute coronary syndrome, were included.

**Adjudication and follow-up.** Two senior clinicians adjudicated for the presence independently for any major adverse cardiac event. A third senior clinician adjudicated any disagreements with the first two clinicians.

ADAPT-RCT (Randomised Controlled Trial). Study design and population. The ADAPT-RCT was a single-center randomized parallel-group trial with blinded outcome assessments conducted in an academic general and tertiary hospital (Australia New Zealand Clinical Trials Registry number 12610000766011). Participants included adults with acute chest pain consistent with acute coronary syndrome for whom the attending physician planned further observation and troponin testing in the Emergency Department at Christchurch Hospital, Christchurch, New Zealand. Patient recruitment occurred from 11 October 2010 to 4 July 2012, with a 30-day follow-up. From the 635 patients recruited, 540 were included in the validation dataset.

**Adjudication and follow-up.** Adjudication and follow-up were as described for ADAPT-CH.

**EDACS. Study design and population.** EDACS was a pragmatic randomized, controlled trial (Australia New Zealand Clinical Trials Registry number 12613000745741) of adults with suspected acute myocardial infarction. The primary outcome was the proportion of patients discharged to outpatient care within 6 h of attendance without a subsequent major adverse cardiac event within 30 days. There were 558 patients recruited, 279 in each arm. From 558 patients presenting to a single center (Christchurch, New Zealand), 529 were included in the validation cohort.

**Adjudication and follow-up.** Adjudication and follow-up were as described for ADAPT-CH.

**SPACE. Study design and population.** For SPACE, patients presenting to Christchurch Hospital with the primary complaint of chest pain of less than 4 h in duration were offered recruitment into our prospective, observational study (http://www.anzctr.org.au, number 12609000057280). Patients with the primary complaint of acute chest, epigastric, neck, jaw or arm pain suspicious of acute coronary syndrome without obvious noncardiac origin lasting  $\geq$ 20 min were enrolled in accordance with guideline definitions. More general/atypical symptoms (such as fatigue, nausea, vomiting, sweating and faintness) were not used as inclusion criteria, and those on dialysis or with terminal kidney failure were excluded. From the 346, a total of

339 patients were included in the external validation dataset. Blood samples for measurement of high-sensitivity cardiac troponin I (Abbott Laboratories) were taken at 0, 1, 2 and 12–24 h after presentation. Cardiac troponin concentrations from time 0 and 2 h were used for validation of CoDE-ACS models.

Adjudication and follow-up. The adjudicated diagnosis of myocardial infarction was made in accordance with the 2012 European Society of Cardiology (ESC)/ American College of Cardiology Foundation (ACCF), American Heart Association (AHA)/World Heart Federation (WHF) task force guidelines by two independent cardiologists with access to all clinical data from standard care. The biochemical component of the diagnosis of myocardial infarction was made using a late-generation cardiac troponin I assay with one value in the  $\geq$ 99th percentile upper reference limit (0.03 µg l<sup>-1</sup>) and a rise or fall of 50% of the reference limit (0.015 µg l<sup>-1</sup>) within 12 h of presentation. At 45 and 365 days following discharge, enrolled patients were contacted by telephone or in writing to complete a follow-up interview/questionnaire. Reported clinical events were identified from the patients themselves (or their primary physician) and confirmed by clinical adjudication, centralized New Zealand Ministry of Health database registry entries on mortality and events, and records of the treating institution.

UTROPIA. Study design and population. UTROPIA was a prospective cohort study enrolling consecutive, unselected patients who presented from 4 February 2014 through 9 May 2014 to the emergency department, in whom serial cardiac troponin I measurements (0, 3, 6 and 9 h) were ordered on clinical indication at Hennepin County Medical Center (NCT02060760) to rule in or rule out acute myocardial infarction. The study protocol was approved by the institutional review committee. For inclusion, patients needed a baseline cardiac troponin I measurement at presentation, at least one additional cardiac troponin I measurement within 24 h of presentation before discharge and at least one 12-lead ECG performed. Exclusion criteria were younger than 18 years old, ST-segment elevation myocardial infarction, pregnancy, trauma, declined to participate, did not present through the emergency department, or the patient was transferred from an outside hospital. For patients with more than one presentation during the study period, only the first presentation was included.

Adjudication. All patients with at least one cardiac troponin I measurements above the 99th percentile were adjudicated according to the Third Universal Definition of Myocardial Infarction consensus recommendations by two clinicians following review of all available medical records, including the 12-lead ECG, echocardiography, angiography, cardiac troponin I results and clinical presentation. Patients in whom there was a discrepancy in the diagnosis were reviewed and adjudicated by a third senior clinician.

#### Comparison with other pathways

We compared CoDE-ACS with the HEART pathway and the 0/1-h pathway recommended by the European Society of Cardiology. The HEART (History, Electrocardiogram, Age, Risk factors and Troponin) pathway identifies low- and high-probability patients with a HEAR (History, Electrocardiogram, Age, and Risk factors) score of less than or equal to three and negative cardiac troponin concentrations at 0 and 3 h and a HEAR score greater than or equal to four or positive cardiac troponin concentrations at 0 or 3 h, respectively<sup>34</sup>. We used the sex-specific 99th percentile to define positive or negative cardiac troponin concentrations within the HEART pathway. The 0/1-h pathway identifies patients at low risk with either very low cardiac troponin concentrations at presentation or low concentrations in combination with a small absolute change at 1 h. It identifies patients at high risk with either very high cardiac troponin concentrations at presentation or a relevant absolute change at 1 h (ref. 12). The High-STEACS trial was registered (ClinicalTrials.gov registry number NCT01852123) and approved by the Scotland A Research Ethics Committee, by the Public Benefit and Privacy Panel for Health and Social Care, and by each National Health Service Health Board<sup>25</sup>. This analysis was prespecified in the trial protocol and was performed according to a separate statistical analysis plan. As the trial intervention was implemented at the hospital level, consent was not sought from individual patients. All data were collected prospectively from the electronic patient record, deidentified and linked to regional and national registries in a data repository within a Secure Data Environment (DataLoch). All cohort studies contributing to the external validation were approved by their respective local research ethics committee or institutional review board with written informed consent from participants.

#### **Reporting summary**

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

#### **Data availability**

The High-Sensitivity Troponin in the Evaluation of Patients with Suspected Acute Coronary Syndrome trial makes use of several routine electronic health care data sources that are linked, deidentified and held in a Secure Data Environment by DataLoch (https://dataloch.org/), which is accessible by approved individuals who have undertaken the necessary governance training. Access to these data and those from the external validation datasets of Advantageous Predictors of Acute Coronary Syndromes Evaluation, Improved Assessment of Chest Pain Trial, 2-Hour Accelerated Diagnostic Protocol to Assess Patients with Chest Pain Symptoms Using Contemporary Troponins as the Only Biomarker, Emergency Department Assessment of Chest Pain Score, Signal Peptide in Acute Coronary Syndromes cohorts from Switzerland, Spain, Poland, Czech Republic, Australia, New Zealand and the United States can be obtained by contacting the corresponding author.

#### **Code availability**

The R code used to evaluate the Collaboration for the Diagnosis and Evaluation of Acute Coronary Syndrome (CoDE-ACS) models is available through GitHub (https://github.com/DimitriosDoudesis/ CoDE-ACS-NatureMedicine), and we have created an evaluation tool in R-shiny to enable other researchers to run the CoDE-ACS models using individual patient-level data (https://decision-support.shinyapps.io/ code-acs/). The datasets used to derive the CoDE-ACS models make use of several routine electronic health care data sources that are linked, deidentified and held in a Secure Data Environment by Data-Loch (https://dataloch.org/). Researchers wishing the source data and models to conduct an evaluation of CoDE-ACS at scale should contact the corresponding author to arrange governance training, approvals and access to our Secure Data Environment.

#### Acknowledgements

The research was funded with support from the National Institute for Health Research and NHSX (Grant AI\_AWARDO2322), the British Heart Foundation (Grant RG/20/10/34966) and Wellcome Leap. The analysis was performed within the Secure Data Environment provided by DataLoch (https://dataloch.org/), which is funded by the Data Driven Innovation Programme within the Edinburgh and South East Scotland City Region Deal. D.D. is supported by the Medical Research Council (Grant MR/N013166/1). K.K.L. is supported by the British Heart Foundation (Clinical Research Training Fellowship FS/18/25/33454). J.B. is supported by grants from the University of Basel, the University Hospital of Basel, the Swiss Academy of Medical Sciences, the Gottfried and Julia Bangerter-Rhyner Foundation, the Swiss National Science Foundation (Grant P500PM 206636) and the Edinburgh Doctoral College (scholarship). A. Bularga is supported by the Medical Research Council (Clinical Research Training Fellowship MR/ V007254/1). L.K. is supported by the Swiss Heart Foundation (grant), the University of Basel, the Swiss Academy of Medical Science, the Gottfried and Julia Bangerter-Rhyner Foundation and the Freiwillige Akademische Gesellschaft Basel. J.H.G. is supported by Advance Queensland (fellowship). C.M. has received research support from the Swiss National Science Foundation, the Swiss Heart Foundation, the Commission for Technology and Innovation and the University Hospital Basel. N.L.M. is supported by the British Heart Foundation (Chair Award CH/F/21/90010, Programme Grant RG/20/10/34966 and Research Excellent Award RE/18/5/34216). The views expressed in this publication are those of the authors and not necessarily those of the National Institute for Health Research, NHSX or the Department of Health and Social Care.

#### **Author contributions**

D.D., K.K.L. and N.L.M. conceived the study and its design. CoDE-ACS investigators were responsible for the acquisition of data. D.D. and K.K.L. performed the analysis. D.D., K.K.L., J.B. and N.L.M. interpreted the data. D.D., K.K.L. and N.L.M. drafted the manuscript. D.D., K.K.L., J.B., A. Bularga, A.V.F., C.T., M.T.H.L., P.L.-A., T.N., L.K., M.O.B., L.N., A.A., K.S., F.S.A., W.P., J.H.G., L.C., J.W.P., M.P.T., A.G., C.M. and N.L.M. revised the manuscript critically for important intellectual content. All authors provided their final approval of the version to be published. All authors are accountable for the work.

#### **Competing interests**

K.K.L. has received honoraria from Abbott Diagnostics. J.B. has received honoraria from Siemens, Roche Diagnostics, Ortho Clinical Diagnostics and Quidel Corporation. P.L.-A. has received speaker's honoraria or consultancy from Quidel paid to the institution outside the submitted work. L.K. has received honoraria from Roche Diagnostics and Siemens outside the submitted work. F.S.A. has consulted, advised or received honoraria from HyTest Ltd., AWE Medical, Werfen, Siemens Healthineers, Qorvo, Siemens Healthineers and Beckman Coulter. Hennepin Healthcare Research Institute has received research grants from Abbott Diagnostics, Abbott POC, Beckman Dickenson, Beckman Coulter, Ortho Clinical Diagnostics, Roche Diagnostics, Siemens Healthineers and Quidel outside the submitted work. L.C. has received honoraria or consultancy from Abbott Diagnostics, Beckman Coulter and Siemens Healthineers. J.W.P. has undertaken consultancy for Abbott Diagnostics. M.P.T. has received consulting fees or honoraria from Abbott Diagnostics, Roche Diagnostics and Siemens Healthineers; received funding for clinical research from Radiometer; and participated on a Data Safety Monitoring Board/Advisory Board for Abbott Diagnostics, Roche Diagnostics, Siemens Healthineers and Radiometer. C.M. has received research support from Abbott, Beckman Coulter, Brahms, Idorsia, LSI Medience Corporation, Novartis, Ortho Diagnostics, Quidel, Roche, Siemens, Singulex and Sphingotec outside the submitted work as well as speaker honoraria/consulting honoraria from Amgen, Astra Zeneca, Bayer, Boehringer Ingelheim, BMS, Idorsia, Novartis, Osler, Roche and Sanofi all paid to the institution. N.L.M. has received honoraria or consultancy from Abbott Diagnostics, Roche Diagnostics, Siemens Healthineers and LumiraDx. D.D., K.K.L. and N.L.M. are employed by the University of Edinburgh, which has filed a patent on the Collaboration for the Diagnosis and Evaluation of Acute Coronary Syndrome score (patent reference: GB2212464). The remainign authors declare no competing interests. All other authors have

reported that they have no relationships relevant to the contents of this paper to disclose.

#### Article

**Extended Data Fig. 6** | **Diagnostic performance of CoDE- ACS in the external validation cohort using serial troponin results.** (a) Receiver-operatingcharacteristic (ROC) curve illustrating discrimination of the CoDE-ACS for myocardial infarction. (b) Calibration of the CoDE-ACS score with the observed proportion of patients with myocardial infarction. The dashed line represents perfect calibration. Each point represents 100 patients. Patients are grouped as low- (<3), intermediate- (3 to 60) or high-probability ( $\geq$ 61) of myocardial infarction. The darker shaded area represents the 95% confidence interval, while the lighter shaded area the 99% confidence interval.

**Extended Data Fig. 7** | **Diagnostic performance of CoDE- ACS scores on serial troponin testing in the external validation cohort across patient subgroups.** Data are presented as a central estimate with 95% confidence intervals based on the Clopper-Pearson method. (**a**) CoDE-ACS low probability score of less than 3. (**b**) CoDE-ACS high probability score of 61 or more.

Extended Data Fig. 8 | External validation of the performance of the CoDE-ACS pathway in 3,629 women (a) and 6,657 men (b) with possible myocardial infarction.

Extended Data Fig. 9 | Diagnostic performance of the CoDE-ACS score in the external validation cohorts by region (Europe, Australia, New Zealand and United States). Receiver-operating-characteristic (ROC) curve

illustrating discrimination of the CoDE-ACS for myocardial infarction. (**a**) Using the presentation cardiac troponin measurement. (**b**) Using the serial cardiac troponin measurement.

Extended Data Fig. 10 | Diagnostic performance in 5,634 patients of the external validation cohort who had cardiac troponin measurements at presentation and 1 hour to enable (A) CoDE-ACS score to identify patients as low-probability of myocardial infarction and (B) the 0/1-hour pathway

to rule out myocardial infarction at presentation in subgroups. Data are presented as a central estimate with 95% confidence intervals based on the Clopper-Pearson method.

# **Reporting Summary**

Nature Portfolio wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Portfolio policies, see our <u>Editorial Policies</u> and the <u>Editorial Policy Checklist</u>.

#### Statistics

For	all st	atistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.
n/a	Cor	firmed
	$\boxtimes$	The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
	$\boxtimes$	A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
	$\boxtimes$	The statistical test(s) used AND whether they are one- or two-sided Only common tests should be described solely by name; describe more complex techniques in the Methods section.
	$\mid$	A description of all covariates tested
	$\boxtimes$	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
		A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
	$\boxtimes$	For null hypothesis testing, the test statistic (e.g. F, t, r) with confidence intervals, effect sizes, degrees of freedom and P value noted Give P values as exact values whenever suitable.
$\boxtimes$		For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
$\boxtimes$		For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
$\boxtimes$		Estimates of effect sizes (e.g. Cohen's d, Pearson's r), indicating how they were calculated
		Our web collection on <u>statistics for biologists</u> contains articles on many of the points above.

#### Software and code

Policy information about availability of computer code

Data collection The High-STEACS trial makes use of several routine electronic health care data sources that are linked, de-identified, and held in a Secure Data Environment within the National Health Service by DataLoch (https://dataloch.org/), which is accessible by approved individuals who have undertaken the necessary governance training.

Data analysis The R code used to evaluate the CoDE-ACS models is available through GitHub (https://github.com/DimitriosDoudesis/CoDE-ACS-NatureMedicine) and we have created an evaluation tool in R-shiny to enable other researchers to run the CoDE-ACS models using individual patient level data (https://decision-support.shinyapps.io/code-acs/). The datasets used to derive the CoDE-ACS models make use of several routine electronic health care data sources that are linked, de-identified, and held in a Secure Data Environment by DataLoch (https:// dataloch.org/). Researchers wishing the source data and models to conduct an evaluation of CoDE-ACS at scale, should contact the corresponding author to arrange governance training, approvals, and access to our Secure Data Environment. All analyses were performed in R version 4.1.2. The algorithm was developed using the R package 'xgboost' version 1.6.2.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Portfolio guidelines for submitting code & software for further information.

Policy information about <u>availability of data</u>

All manuscripts must include a <u>data availability statement</u>. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A description of any restrictions on data availability
- For clinical datasets or third party data, please ensure that the statement adheres to our policy

The High-STEACS trial makes use of several routine electronic health care data sources that are linked, de-identified, and held in a Secure Data Environment by DataLoch (https://dataloch.org/), which is accessible by approved individuals who have undertaken the necessary governance training. Researchers wishing to access these data should contact the corresponding author to arrange governance training, approvals, and remote access to the Secure Data Environment. The external validation datasets of APACE (Advantageous Predictors of Acute Coronary Syndromes Evaluation), IMPACT (Improved Assessment of Chest pain Trial), ADAPT (2-Hour Accelerated Diagnostic Protocol to Assess Patients With Chest Pain Symptoms Using Contemporary Troponins as the Only Biomarker), EDACS (Emergency Department Assessment of Chest pain Score), SPACE (Signal Peptide in Acute Coronary Events) and UTROPIA (Use of Abbott High Sensitivity Troponin I Assay In Acute Coronary Syndromes) cohorts from Switzerland, Spain, Poland, Czech Republic, Australia, New Zealand and the United States can be accessed by contacting each corresponding author.

#### Human research participants

Policy information about studies involving human research participants and Sex and Gender in Research.

Reporting on sex and gender	Our manuscript is compliant with the journal's policy on sex and gender reporting. Sex was carefully considered in our study design. We previously demonstrated that cardiac troponin concentrations differ between men and women (BMJ. 2015;350:g7873), which informed the current international definition of myocardial infarction (Circulation. 2018;138:e618-e651). Sex is self-reported by patients when they register with the National Health Service, and this was used in the derivation cohorts for our models. In our external validation cohorts, sex was assigned by the researchers. Our models include sex as one of the variables used to estimate the probability of myocardial infarction. We reported a priori the overall performance of our model by sex. However, in our revised manuscript we have also included an additional post hoc evaluation of the diagnostic performance of the CoDE-ACS pathway separately in men and women and have discussed these findings.
Population characteristics	Patients were included in this prespecified secondary analysis based on the following criteria: (1) age ≥18 years old, (2) presentation with suspected acute coronary syndrome, (3) cardiac troponin measured using the ARCHITECTSTAT high-sensitivity cardiac troponin I assay (Abbott Laboratories), (4) availability of electrocardiographic and physiological data for diagnostic adjudication. Patients with a diagnosis of ST-segment elevation myocardial infarction were excluded given they undergo coronary revascularisation directly without troponin testing in the Emergency Department.
Recruitment	The High-STEACS trial population was used for the derivation of the CoDE-ACS (Collaboration for the Diagnosis and Evaluation of Acute Coronary Syndrome) algorithm. As previously described, High-STEACS was a stepped-wedged cluster-randomized controlled trial to evaluate the implementation of a high-sensitivity cardiac troponin I assay in consecutive patients with suspected acute coronary syndrome presenting to ten secondary and tertiary hospitals in Scotland between June 10, 2013, and March 3, 2016. As all consecutive patients were enrolled there is no selection bias in this trial.
Ethics oversight	The High-Sensitivity Troponin in the Evaluation of Patients With Suspected Acute Coronary Syndrome (High-STEACS) trial was registered (www.clinicaltrials.gov NCT01852123) and approved by the Scotland A Research Ethics Committee, the Public Benefit and Privacy Panel for Health and Social Care, and by each National Health Service (NHS) Health Board. This analysis was prespecified in the trial protocol and was performed according to a separate Statistical Analysis Plan. As the trial intervention was implemented at hospital level, consent was not sought from individual patients. All data were collected prospectively from the electronic patient record, deidentified and linked to regional and national registries in a data repository within a National Health Service managed Secure Data Environment (DataLoch, Edinburgh, United Kingdom). All cohort studies contributing to the external validation were approved by their respective local research ethics committee or institutional review board with written informed consent from participants.

Note that full information on the approval of the study protocol must also be provided in the manuscript.

# Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Ecological, evolutionary & environmental sciences

Life sciences

Behavioural & social sciences

# Life sciences study design

Sample size	No prior sample size calculation have been performed. All the available data for this study has been used.
Data exclusions	Patients with a diagnosis of ST-segment elevation myocardial infarction were excluded given they undergo coronary revascularisation directly without troponin testing in the Emergency Department.
Replication	All the analysis is reproducible. A random seed has been used throughout the analysis to make sure that there are no small differences (decimal points) to the results.
Randomization	No randomized comparisons are reported in this analysis.
Blinding	The diagnosis of myocardial infarction and clinical outcomes were adjudicated by a panel of clinicians who were blinded to the trial phase and the CoDE-ACS score.

#### All studies must disclose on these points even when the disclosure is negative.

# Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

#### Materials & experimental systems

#### Methods

n/a	Involved in the study	n/a	Involved in the study	
$\boxtimes$	Antibodies	$\boxtimes$	ChIP-seq	
$\boxtimes$	Eukaryotic cell lines	$\boxtimes$	Flow cytometry	
$\boxtimes$	Palaeontology and archaeology	$\boxtimes$	MRI-based neuroimaging	
$\boxtimes$	Animals and other organisms			
	🔀 Clinical data			
$\boxtimes$	Dual use research of concern			

#### Clinical data

Policy information about <u>clinical studies</u>

All manuscripts should comply with the ICMJE guidelines for publication of clinical research and a completed CONSORT checklist must be included with all submissions.

Clinical trial registration	NCT01852123
Study protocol	Study protocol is available through the trial registration site (https://clinicaltrials.gov/ProvidedDocs/23/NCT01852123/Prot_000.pdf)
Data collection	All consecutive patients with suspected acute coronary syndrome presenting to ten secondary and tertiary hospitals in Scotland between June 10, 2013, and March 3, 2016.
Outcomes	The model was trained to identify patients with an adjudicated diagnosis of type 1, type 4b or type 4c myocardial infarction during the index hospital admission. All primary and secondary outcomes were prespecified in the trial protocol. The diagnosis of myocardial infarction was adjudicated according to the Fourth Universal Definition of Myocardial Infarction by two clinicians independently, with a third reviewer providing consensus if there was disagreement. Regional and national registries were used to follow-up the trial population for one year. The cause of death was adjudicated by investigators masked to troponin concentrations during the index presentation.
