

Nuclear E-cadherin and VHL immunoreactivity are prognostic indicators of clear-cell renal cell carcinoma

Michelle L Gervais¹, Pauline C Henry², Arthy Saravanan², T Nadine Burry¹, Brenda L Gallie³, Michael AS Jewett⁴, Richard P Hill⁵, Andrew J Evans² and Michael Ohh¹

The loss of functional von Hippel–Lindau (VHL) tumor suppressor gene is associated with the development of clear-cell renal cell carcinoma (CC-RCC). Recently, VHL was shown to promote the transcription of E-cadherin, an adhesion molecule whose expression is inversely correlated with the aggressive phenotype of numerous epithelial cancers. Here, we performed immunohistochemistry on CC-RCC tissue microarrays to determine the prognostic value of E-cadherin and VHL with respect to Fuhrman grade and clinical prognosis. Low Fuhrman grade and good prognosis associated with positive VHL and E-cadherin immunoreactivity, whereas poor prognosis and high-grade tumors associated with a lack of E-cadherin and lower frequency of VHL staining. A significant portion of CC-RCC with positive VHL immunostaining correlated with nuclear localization of C-terminally cleaved E-cadherin. DNA sequencing revealed in a majority of nuclear E-cadherin-positive CC-RCC, subtle point mutations, deletions and insertions in VHL. Furthermore, nuclear E-cadherin was not observed in chromophobe or papillary RCC, as well as matched normal kidney tissue. In addition, nuclear E-cadherin localization was recapitulated in CC-RCC xenografts devoid of functional VHL or reconstituted with synthetic mutant VHL grown in SCID mice. These findings provide the first evidence of aberrant nuclear localization of E-cadherin in CC-RCC harboring VHL mutations, and suggest potential prognostic value of VHL and E-cadherin in CC-RCC.

KEYWORDS: CC-RCC; nuclear E-cadherin; prognostic indicators; tissue microarray; VHL

Renal cell carcinoma (RCC) accounts for approximately 3% of all adult malignancies, with the clear-cell type (CC-RCC) comprising 80% of RCC.^{1,2} Approximately 25–30% of CC-RCC patients have metastatic disease at diagnosis, and 20–30% of patients with clinically localized CC-RCC develop metastasis post-nephrectomy.³ Recent advances in the use of antiangiogenesis-targeted agents appear to have revolutionized treatment.^{4–7} Currently, a prediction of patient survival is based on traditional clinical parameters, including tumor size and Fuhrman nuclear grade.⁸ However, the emerging understanding of the molecular pathways implicated in CC-RCC genesis and progression is providing previously unappreciated markers, which may serve as additional or better prognostic indicators of CC-RCC.

The principal cause of sporadic CC-RCC and familial von Hippel–Lindau (VHL) disease-associated CC-RCC is the inactivating mutations of *VHL*. Although VHL patients also

develop tumors in other organs including the central nervous system, retina and the adrenal gland, CC-RCC remains to be the leading cause of morbidity and death for VHL patients.⁹ The most well-established function of VHL is its role in the oxygen-dependent negative regulation of hypoxia-inducible factor (HIF). VHL is a substrate-conferring component of an E3 ubiquitin ligase ECV (elongins/Cul2/VHL) that polyubiquitylates the catalytic α -subunit of HIF that has undergone hydroxylation on conserved prolyl residues within the oxygen-dependent degradation (ODD) domain. Prolyl hydroxylation is mediated by a class of prolyl hydroxylases (PHD1–3) in an oxygen-dependent manner. Thus, under hypoxia or in the absence of a functional VHL, HIF α becomes stabilized and binds to its common and constitutively expressed β -subunit, forming an active HIF transcription factor capable of transactivating numerous hypoxia-inducible genes such as *vascular endothelial growth factor (VEGF)*,

glucose transporter-1 (*GLUT1*) and erythropoietin (*EPO*).⁹ These discoveries have confirmed VHL as a critical regulator of the ubiquitous mammalian oxygen-sensing pathway.

HIF α is overexpressed in most tumors including CC-RCC. The re-introduction of VHL into *VHL-null* CC-RCC abrogates the tumorigenic potential of these cells in a mouse xenograft model.^{10,11} Kondo *et al*¹² have shown that the expression of a non-degradable form of HIF2 α was able to restore the tumorigenic phenotype in CC-RCC cells ectopically expressing VHL. Conversely, shRNA-mediated knock-down of HIF2 α was sufficient to suppress the tumorigenic capacity of VHL-null CC-RCC cells.¹³ Notably, the emerging evidence suggests that *VHL* mutations affecting HIF regulation were invariably associated with a subtype of VHL disease with a greater propensity of CC-RCC. Although these reports support the notion that deregulated accumulation of HIF α upon the loss of VHL is crucial for the development of CC-RCC, the precise downstream target(s) of HIF that are responsible for renal epithelial oncogenesis have, until recently, remained unclear.

The regulation of adhesive interactions between cells is critical during cell growth and differentiation, and the loss of cell-cell adhesion is frequently associated with tumor progression and metastasis.¹⁴ Recently, VHL was shown to promote the transcription of E-cadherin via HIF-dependent activation of E-cadherin-specific transcriptional repressors.¹⁵⁻¹⁷ Thus, a loss of VHL in CC-RCC results in the hyperactivation of HIF that triggers the expression of E-cadherin repressors, which in turn attenuates the expression of E-cadherin.¹⁵⁻¹⁷ E-cadherin, a homophilic adhesion molecule associated with catenins that functions as a major component of cell junctions in polarized epithelial cells, is an established tumor suppressor. The graded loss of E-cadherin correlates with the aggressiveness of numerous carcinomas and the worsening of prognosis, while forced expression of E-cadherin suppresses tumor development and invasion in various *in vitro* and *in vivo* tumor model systems.¹⁴

The full-length E-cadherin (120 kDa) can be proteolytically cleaved at a cleavage site near the transmembrane domain, which releases an extracellular N-terminal 80-kDa fragment and generates a 38-kDa C-terminal fragment that can be further processed into a 33-kDa soluble cytosolic fragment.¹⁸ The proteolytic ectodomain release or 'shedding' of E-cadherin is emerging as an important regulatory mechanism and has been suggested to cause rapid changes in cell adhesion, signaling and apoptosis.¹⁹⁻²² Furthermore, increased levels of the soluble N-terminal fragment have been associated with several tumors, including prostate,²³ gastric,²⁴ hepatocellular²⁴ and bladder cancer and may be of prognostic value.²¹ Whether the C-terminal intracellular fragment of E-cadherin has oncogenic roles, for example, via promoting β -catenin-mediated signaling, is unclear.

Here, we examined the prognostic value of VHL and E-cadherin in CC-RCC. While CC-RCC with negative E-cadherin staining exhibited no VHL immunoreactivity as

expected, a significant portion of CC-RCC had aberrant nuclear E-cadherin staining despite positive VHL staining. DNA sequencing revealed in a majority of the nuclear E-cadherin-positive CC-RCC, subtle point mutations, deletions and insertions in *VHL*. The nuclear E-cadherin was not observed in chromophobe or papillary RCC, suggesting this to be specific to CC-RCC. Low Fuhrman grade and better prognosis associated with positive VHL and nuclear E-cadherin immunoreactivity, whereas high-grade tumors associated with a lack of nuclear E-cadherin staining and lower frequency of VHL staining. These findings provide the first evidence of an aberrant nuclear localization of E-cadherin in CC-RCC harboring VHL mutations, and suggest potential prognostic value of VHL and E-cadherin status in CC-RCC.

MATERIALS AND METHODS

Cell Culture

Human 786-O CC-RCC cells were cultured in Dulbecco's modified Eagle's medium containing 10% heat-inactivated fetal bovine serum (Sigma, Saint Louis, MI, USA) at 37°C in a humidified 5% CO₂ atmosphere. 786-O subclones stably expressing hemagglutinin (HA)-tagged wild-type VHL30, HA-VHL19(WT), HA-VHL19(MUT) with V84M and P192Q mutations, or empty plasmid were generated as previously described.^{25,26}

Antibodies

Anti-HA (12CA5; Roche Applied Science, Basel, Switzerland), anti-TCP1 (Abcam Inc., Cambridge, MA, USA), C-terminal-specific anti-E-cadherin (BD Biosciences, Mississauga, ON, Canada), N-terminal-specific anti-E-cadherin (Vector laboratories, Burlingame, CA, USA), anti-VHL (IG32) (BD Biosciences, Mississauga, ON, Canada), and anti- β -catenin (BD Biosciences, Mississauga, ON, Canada) monoclonal antibodies and anti-Glut1 polyclonal antibodies (Alpha Diagnostic International Inc., San Antonio, TX, USA) were obtained from the companies indicated.

Plasmids

The mammalian expression plasmid pRc-CMV-HA-VHL30 was previously described.^{25,26} pRc-CMV-HA-VHL19(WT) was generated from the pRc-CMV-HA-VHL30 plasmid using primer set 5'-CCCAAGCTTATGTATCCATATGATGTTCCA GATTATGCTGAGGCCGGCGGCCG-3'/5'-GCTCTAGATC AATCTCCCATCCGTTGATGTGC-3'. pRc-CMV-VHL19(MUT), V84M and P192Q, was serendipitously generated from pRc-CMV-HA-VHL30 using the above primers in a PCR reaction. The authenticity of the plasmids was confirmed by direct DNA sequencing.

Immunoprecipitation and Immunoblotting

Cells were lysed in EBC buffer (50 mM Tris (pH 8), 120 mM NaCl, 0.5% NP-40) supplemented with protease and phosphatase inhibitors (Roche, Laval, QC, Canada). Samples were supplemented with the indicated antibody and immobilized

on protein A-Sepharose beads (Amersham Biosciences, Uppsala, Sweden). The samples were then washed five times with NETN buffer (20 mM Tris (pH 8), 120 mM NaCl, 1 mM EDTA, 0.5% NP-40), eluted by boiling in sodium dodecyl sulfate (SDS)-containing sample buffer, separated by SDS-polyacrylamide gel electrophoresis (PAGE) and electro-transferred to a polyvinylidene difluoride membrane (Bio-Rad, Mississauga, ON, Canada). Specific protein bands on Western blots were visualized using the various antibodies indicated. All primary antibodies were diluted in phosphate-buffered saline (PBS) containing 0.1% Tween 20. Horseradish peroxidase-conjugated goat anti-mouse, goat anti-rabbit or rabbit anti-goat antibody (Pierce, Rockford, IL, USA) was used at 1:20 000 dilution as a secondary antibody, after which enhanced chemiluminescence (PerkinElmer Life Sciences, Woodbridge, ON, Canada) was performed for detection.

Metabolic Labeling

Metabolic labeling was performed as previously described.²⁷ Briefly, radioisotope labeling was performed by methionine starvation for 45 min, followed by growth in 5 ml of methionine-free Dulbecco's modified Eagle's medium supplemented with [³⁵S]methionine (100 μ Ci/ml of medium; PerkinElmer Life Sciences, Woodbridge, ON, Canada) and 2% dialyzed fetal bovine serum at 37°C in a humidified 5% CO₂ atmosphere for 3 h for the interaction studies and 1 h for half-life analysis.

RNA Extraction

RNA was extracted from cells using RNeasy kit according to the manufacturer's instructions (Qiagen, Mississauga, ON, Canada).

Quantitative Real-Time PCR

Quantitative real-time PCR was performed as previously described.²⁸ Briefly, first-strand cDNA synthesis was performed as follows: 1 μ l of oligo(dT)₂₃ primer (Sigma, St Louis, MI, USA) was incubated with 5 μ g of RNA and dH₂O (total reaction volume was 20 μ l) for 10 min at 70°C in a thermal cycler (MJ research, Boston, MA, USA). The mixture was cooled to 4°C, at which time 4 μ l of 5 \times first-strand reaction buffer, 2 μ l of 0.1 M DTT, 1 μ l of 10 mM dNTPs and 1 μ l Superscript II reverse transcriptase (Invitrogen, Carlsbad, CA, USA) were added. cDNA synthesis was performed for 1.5 h at 42°C, followed by 15 min at 70°C in the thermal cycler. Human genomic DNA (Roche, Mannheim, Germany) standards or cDNA equivalent to 20 ng of total RNA were added to the qPCR reaction in a final volume containing 1 \times PCR buffer (without MgCl₂), 3 mM MgCl₂, 0.25 U Platinum Taq DNA polymerase, 0.2 mM dNTPs, 0.3 μ l SYBR Green I, 0.2 μ l ROX reference dye and 0.5 μ M primers (Invitrogen, Carlsbad, CA, USA). Amplification conditions were as follows: 95°C (3 min); 40 cycles of 95°C (10 s), 65°C (15 s), 72°C (20 s), 60°C (15 s) and 95°C (15 s). qPCR was performed using the ABI Prism 7900HT Sequence Detection System

(Applied Biosystems, Foster City, CA, USA). Gene-specific oligonucleotide primers designed using Primer Express (Applied Biosystems) were as follows: *GLUT-1* primer set 1 (5'-CACCACCTCACTCCTGTTACTTACCT-3' and 5'-CAAG CATTTCAAAACCATGTTTCTA-3'), *GLUT-1* primer set 2 (5'-CTCCCAGCAGCCCTAAGGAT-3' and 5'-ATCTGTCAG GTTTGGAAGTCTCATC-3') and β -*actin* primer set (5'-GGA TCGGCGGCTCCAT-3' and 5'-CATACTCCTGCTTGCTGAT CCA-3'). SYBR I fluoresces during each cycle of the qPCR by an amount proportional to the quantity of amplified cDNA (the amplicon) present at that time. The point at which the fluorescent signal is statistically significant above the background is defined as the cycle threshold (C_t). Expression levels of the various transcripts were determined by taking the average C_t value for each cDNA sample performed in triplicate, and measured against a standard plot of C_t values from amplification of serially diluted human genomic DNA standards. Since the C_t value is inversely proportional to the log of the initial copy number, the copy number of an experimental mRNA can be obtained from linear regression of the standard curve. A measure of the fold difference in copy number was determined for each mRNA. Values were normalized to the expression of β -*actin* mRNA and represent the average value of both *GLUT-1* primers in three independent experiments performed in triplicate.

In Vitro Ubiquitination Assay

An *in vitro* ubiquitination assay was performed as previously described.²⁹ The [³⁵S]methionine-labeled reticulocyte lysate HA-HIF-1 α ODD translation product (4 μ l) was incubated in 786-O RCC S100 extracts (100–150 μ g) supplemented with 8 μ g/ μ l ubiquitin (Sigma), 100 ng/ μ l ubiquitin aldehyde (Boston Biochem Inc., Cambridge, MA, USA) and an ATP-regenerating system (20 mM Tris (pH 7.4), 2 mM ATP, 5 mM MgCl₂, 40 mM creatine phosphate and 0.5 μ g/ μ l creatine kinase) in a reaction volume of 20–30 μ l for 1.5 h at 30°C.

Protease Digestion Assay

Protease sensitivity was assayed as previously described.³⁰ Briefly, lysates were incubated with chymotrypsin (10 μ g/ml) for 10 min on ice. Reactions were stopped by the addition of 1 mM PMSF before immunoprecipitation (IP) and SDS-PAGE.

SCID Mouse Xenograft Assay

Multiple 786-O subclones expressing HA-VHL30, HA-VHL19(MUT) or empty plasmid were grown to ~90% confluence in a humidified 5% CO₂ atmosphere at 37°C. Cells were harvested with a solution of 0.25% trypsin and 1 mM EDTA. Cells (1×10^7) in 100 μ l of 1 \times PBS were injected intramuscularly into the left hind legs of male SCID mice (Charles River Laboratories Inc., Wilmington, MA, USA). Tumor growth was assessed and measured weekly by carefully passing the tumor-bearing leg through a series of

holes of decreasing diameter (0.5-mm decrements) in a plastic rod.

Immunohistochemistry

SCID mouse xenograft tumors were fixed in 10% neutral buffered formalin and later embedded in paraffin. Formalin-fixed, paraffin-embedded sections from 19 nephrectomy specimens with CC-RCC were obtained from the Department of Pathology and Laboratory Medicine at The University Health Network (Toronto, ON, Canada). These tissue blocks were used and processed in accordance with a University Health Network Research Ethics Board-approved protocol concerning gene expression in RCC. Tissues were fixed in 10% neutral buffered formalin for 24–36 h. Representative sections of tumor with adjacent non-tumor renal parenchyma, 3–4 mm in thickness, were embedded in paraffin and 5- μ m sections were cut and placed on coated slides for light microscopy.

Tumor morphology and classification were assessed using standard hematoxylin and eosin (H&E) staining. The tumors were classified as conventional clear-cell type according to criteria described in the WHO classification of renal tumors.³¹ Immunohistochemical staining for VHL was performed manually using a standard avidin–biotin–peroxidase complex method. Briefly, unlabeled anti-HA, anti-Glut1, anti-E-cadherin (BD biosciences, Mississauga, ON, Canada), anti-E-cadherin (Vector laboratories, Burlingame, CA, USA) and anti- β -catenin were used at a 1:2000 dilution, and an overnight incubation following microwave pretreatment for antigen retrieval. The sections were then incubated with a biotinylated secondary antibody (horse anti-mouse IgG, 1:200 dilution) and the avidin–peroxidase complex. The colored reaction was visualized using nova red as the chromogen. The tissue was then mildly counterstained with hematoxylin.

Tissue Microarray

Tissue microarray (TMA) consisting of quadruplicate representative 1.0-mm cores from 56 CC-RCC with various Fuhrman grades (grades 1–4) and stages (pT1–pT4) were used to analyze the correlation between E-cadherin and VHL protein expression. Sections (5 μ m) from the CC-RCC TMA were stained with anti-E-cadherin and anti-VHL antibodies as described above. The slides were then scanned using a ScanScope (Aperio Technologies, Vista, CA, USA) and scored by two observers. In order to be considered for evaluation, at least half of the TMA core was required to be present on the slide, with at least 50% of the tissue present being tumor cells. Cores were being scored as either positive or negative. Only tumors with the majority of cores in agreement (3 out of 4 or 2 out of 3) were used for further analysis.

VHL Sequencing

VHL was amplified from patient samples using primers 5'-CAGTAACGAGTTGGCCTAGC-3'/5'-GGATGTGTCCTG

CCTCAAG-3' for exon 1, 5'-GGACGGTCTTGATCTCCTGA-3'/5'-GATTGGATACCGTGCCTGAC-3' for exon 2 and 5'-CTGCCACATACATGCACTCA-3'/5'-AAGGAAGGAACCAGTCC TGT-3' for exon 3. PCR reactions were performed using the Qiagen Multiplex Master Mix (Qiagen, Mississauga, ON, Canada) according to manufacturer's instructions. Exons were sequenced with the Cy5/Cy5.5 Dye Primer Cycle Sequencing kit (Amersham, Quebec/Visible Genetics, Toronto) according to the manufacturer's instructions. Each primer mixture contained two primers, labeled with either Cy5 or Cy5.5. Primers used for sequencing were 5'-/5Cy5/-CTAGCCTCGCCTCCGT TA-3'/5'-/5Cy5/-GCCTCAGTTCCCCGTCTG-3' for exon 1, 5'-/5Cy5/-GATACCGTGCCTGACATCAG-3' for exon 2 and 5'-/5Cy5/-CAGGTAGTTGTTGGCAAAGC-3' for exon 3. Two primers were used for exon 1 as it is a large exon. The sequences generated were compared with wild-type VHL (GenBank accession number AC_000046) for sequence alterations, using the OpenGene Automated DNA System and Gene Librarian software, version 3.1 (Visible Genetics, Suwanee, GA, USA).

Statistics

Fisher's exact test was used to determine whether positive VHL immunoreactivity and nuclear E-cadherin subcellular localization were interdependent. Two-tailed *P*-values less than 0.05 were considered significant.

RESULTS

Nuclear Localization of E-cadherin is Associated with CC-RCC-Harboring VHL Mutation

VHL acts as the substrate-recognition moiety of an E3 ubiquitin ligase that ubiquitylates HIF α for 26S proteasome-mediated destruction. Recently, we and others have shown that upon the loss of VHL, HIF negatively regulates the transcription of E-cadherin by upregulating the transcriptional repressors of E-cadherin.^{15–17} Consequently, CC-RCC cells devoid of VHL fail to express E-cadherin.^{15–17} Although CC-RCC on TMA with negative VHL immunoreactivity correlated with negligible E-cadherin staining as predicted, a significant portion (49% or 22/45) of the samples that met the quality standard criteria (see Materials and Methods) showed previously undocumented nuclear E-cadherin localization (Figure 1a, left panel). The majority (77% or 17/22) of these 22 nuclear E-cadherin-positive samples stained positive, while 14% (3/22) negative and 9% (2/22) uncertain for VHL, indicating a statistically significant correlation between nuclear E-cadherin staining and positive VHL immunoreactivity (*P* = 0.009) (Figure 1a, right panel). Of the 23 CC-RCC samples that were negative for nuclear E-cadherin, 39% (9/23) were positive, 48% (11/23) were negative and 13% (3/23) were inconclusive for VHL immunoreactivity.

The vast majority (approximately 80%) of CC-RCC have VHL mutations. Thus, a positive VHL immunostaining would not necessarily indicate a wild-type VHL status. We next determined via direct DNA sequencing the VHL status

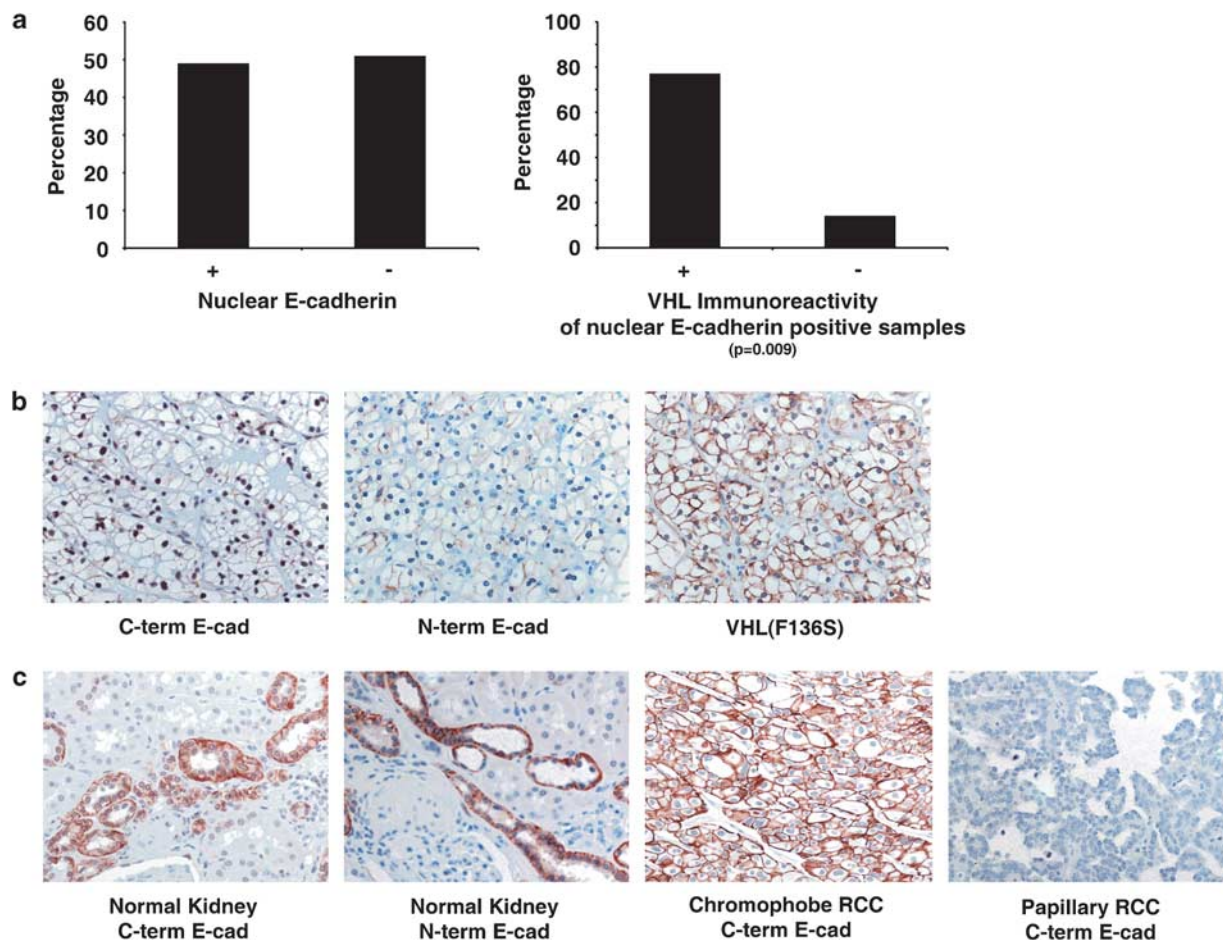

Figure 1 Nuclear localization of E-cadherin correlates with positive VHL immunostaining in CC-RCC. **(a)** CC-RCC TMA were immunostained with anti-E-cadherin antibody and scored for nuclear E-cadherin expression (left panel). Nuclear E-cadherin-positive CC-RCC samples were then scored for VHL immunoreactivity (right panel). **(b)** Immunohistochemical staining of a representative tumor tissue sample (patient no. 9) with VHL mutation using the indicated antibodies. **(c)** Immunohistochemical staining of a representative normal kidney tissue sample (patient no. 9), as well as representative samples on TMA slide constructed using quadruplicate samples from chromophobe and papillary RCC subtypes using the indicated antibodies. Notably, chromophobe RCC is known to express E-cadherin, while papillary RCC has been shown to be a non-expresser of E-cadherin.³²

of CC-RCC samples with positive nuclear E-cadherin staining. Seventeen of the 22 nuclear E-cadherin-positive CC-RCC samples were available for *VHL* sequencing. Of these 17 samples, 13 stained positive for VHL, two were negative and two had indeterminate VHL staining. Consistent with the prevalence of VHL inactivation in CC-RCC, we found VHL mutations in 62% (8/13) of CC-RCC samples that stained positively for VHL (Table 1). Therefore, a high percentage of CC-RCC with nuclear E-cadherin staining contained detectable VHL mutations despite positive VHL immunoreactivity. Moreover, we found that the two samples that had negative staining for VHL (sample number 18 and 19) harbored VHL mutations, indicating that these mutations may have affected the ability of VHL to be recognized by anti-VHL antibody, and one of the two samples that had uncertain VHL staining (sample number 17) had VHL mutation. Although unable to establish statistical significance due to currently available small sample size, nuclear E-cadherin

staining showed a positive trend with the presence of a VHL mutation. Notably, nuclear E-cadherin is likely a cleavage product of the membranous full-length E-cadherin (discussed below). In keeping with this notion, a significant portion of CC-RCC samples with nuclear E-cadherin staining also exhibited membranous E-cadherin staining (Table 1).

E-cadherin is a type I transmembrane glycoprotein that has been shown to be proteolytically cleaved in its transmembrane domain, resulting in an 80-kDa N-terminal soluble fragment and an intracellular C-terminal fragment.²¹ We asked whether the observed nuclear E-cadherin in CC-RCC is the full-length protein or a truncated form. TMA were immunostained with an anti-E-cadherin antibody generated against the N-terminus or C-terminus of E-cadherin. While both antibodies immunostained membranous E-cadherin, the nuclear E-cadherin was exclusively recognized by the C-terminus-specific anti-E-cadherin antibody, as illustrated

CC-RCC, clear-cell renal cell carcinoma; N/A, not available; VHL, von Hippel-Lindau.

*WT indicates wild-type; + indicates 3 or 4 cores out of four stained positive; ± indicates 2 cores out of four stained positive; – indicates 0 or 1 core out of four stained positive.

in the representative Figure 1b (and data not shown) representing a CC-RCC sample from patient no. 9 shown to have F136S substitution mutation in VHL (Table 1). Notably, the normal kidney tissue from patient no. 9 showed an archetypal membranous E-cadherin staining of the proximal tubule cells, regardless of the antibody used and, importantly, no nuclear localization of E-cadherin was observed (Figure 1c). We next asked if nuclear localization of E-cadherin is a phenomenon unique to CC-RCCs. We stained a TMA slide constructed using quadruplicate samples from chromophobe and papillary RCC subtypes with the C-terminal E-cadherin antibody that showed nuclear staining in the CC-RCC cases. Chromophobe RCC has been reported to express E-cadherin, while papillary RCC has been shown to be a non-expresser of E-cadherin.³² As expected, chromophobe RCC cells exhibited membranous E-cadherin immunoreactivity, but no nuclear protein was found. Papillary RCC was negative for E-cadherin immunoreactivity (Figure 1c). These results suggest that the aberrant nuclear localization of C-terminal E-cadherin is specific to RCC of clear-cell type.

The Synthetic VHL19 Mutant Exhibits the Biochemical Signature of a Disease-Prone Mutation

The molecular validation of critical pathways implicated in VHL-associated CC-RCC development and progression has been widely studied in immune-compromised Nude or SCID mice. We asked whether the aberrant nuclear localization of E-cadherin is recapitulated in human CC-RCC xenograft transplanted in SCID mice. VHL gene produces two wild-type forms, a full-length VHL30 and an internally translated VHL19.^{33–35} Although ectopic expression of either isoform has been shown to suppress CC-RCC tumor formation in Nude mice,^{10,11,33,35} demonstrating that both isoforms possess tumor suppressor functions, VHL19 is more abundantly produced than VHL30. Therefore, the general perception is that VHL19 is the dominant isoform, at least, in cell lines. However, mutations in the context of VHL19 have not been examined in a mouse xenograft assay.

No disease-causing mutation in the exclusive context of VHL19 has been reported. Thus, we generated 786-O

CC-RCC subclones stably expressing HA-VHL19(MUT) with synthetic V84M and P192Q substitutions, which would simultaneously represent α - and β -domain-related VHL mutations based on the reported crystal structure of VHL19/elongin B/elongin C complex.³⁶ Cells expressing HA-VHL19(MUT), HA-VHL19(WT) or empty plasmid were metabolically labeled with [³⁵S]methionine, lysed, immunoprecipitated with an anti-HA antibody and the bound proteins were resolved by SDS-PAGE (Figure 2a). In comparison with HA-VHL19(WT) or HA-VHL30(WT), which generated similar associated-protein profile as expected,^{37–39} HA-VHL19(MUT) was deficient in co-precipitating elongins B/C and Cullin 2 (Cul2), the components of the ECV complex (Figure 2a; Supplementary Figure 1). Consistent with reduced elongin/Cul2 binding, 786-VHL19(MUT) showed reduced HIF α (ODD) ubiquitylation in an *in vitro* ubiquitination assay and CC-RCC cells expressing VHL19(MUT) had correspondingly increased level of HIF-target *GLUT1* expression under normal oxygen tension (Supplementary Figure 2). Although there are conflicting reports with regards to VHL19–fibronectin interaction, possibly due to the heterogeneity of cultured CC-RCC cell lines,^{34,37} we found that HA-VHL19(WT) but not HA-VHL19(MUT) co-precipitated fibronectin (Figure 2a). Moreover, VHL30(WT) has previously been shown to associate with the eukaryotic chaperonin TRiC/CCT complex (see also Supplementary Figure 1).^{40–42} Proper TRiC-mediated folding of VHL30 is required for binding elongins B/C and VHL disease-causing mutants have been shown to have elevated binding of the TRiC complex.^{40–42} Indicative of a mutant phenotype, HA-VHL19(MUT) showed markedly increased binding of the TRiC complex, including one of the components TCP1, than HA-VHL19(WT) or HA-VHL30(WT) (Figure 2a and b; Supplementary Figure 1). A consequence of increased TRiC interaction is the attenuated resistance to protease digestion, suggesting that a mutant VHL has a loose unfolded structure that is sensitive to proteases such as chymotrypsin and thermolysin.³⁰ In accordance, HA-VHL30(WT) was resistant to protease digestion as expected, whereas HA-VHL19(MUT) was sensitive to chymotrypsin (Figure 2c). HA-VHL30(C162F) served as a positive control for protease sensitivity (Figure 2c), as this disease-causing mutant is incapable of binding elongin C and remains bound to the TRiC

complex.^{36,42} We next asked whether the sensitivity to protease digestion correlated with shortened half-life. 786-MOCK, 786-VHL30 and 786-VHL19(MUT) cells were pulsed with [³⁵S]methionine for 1 h (or treated with cyclohexamide; data not shown) and chased for the indicated number of hours (Figure 2d). As expected, HA-VHL30 had a long protein half-life, whereas HA-VHL19(MUT) had a dramatically shortened half-life (Figure 2d). These results taken together demonstrate that HA-VHL19(MUT) has all the biochemical signatures of a defective, disease-prone VHL mutation.

CC-RCC Tumor Xenograft in SCID Mice Exhibits Nuclear E-Cadherin Expression

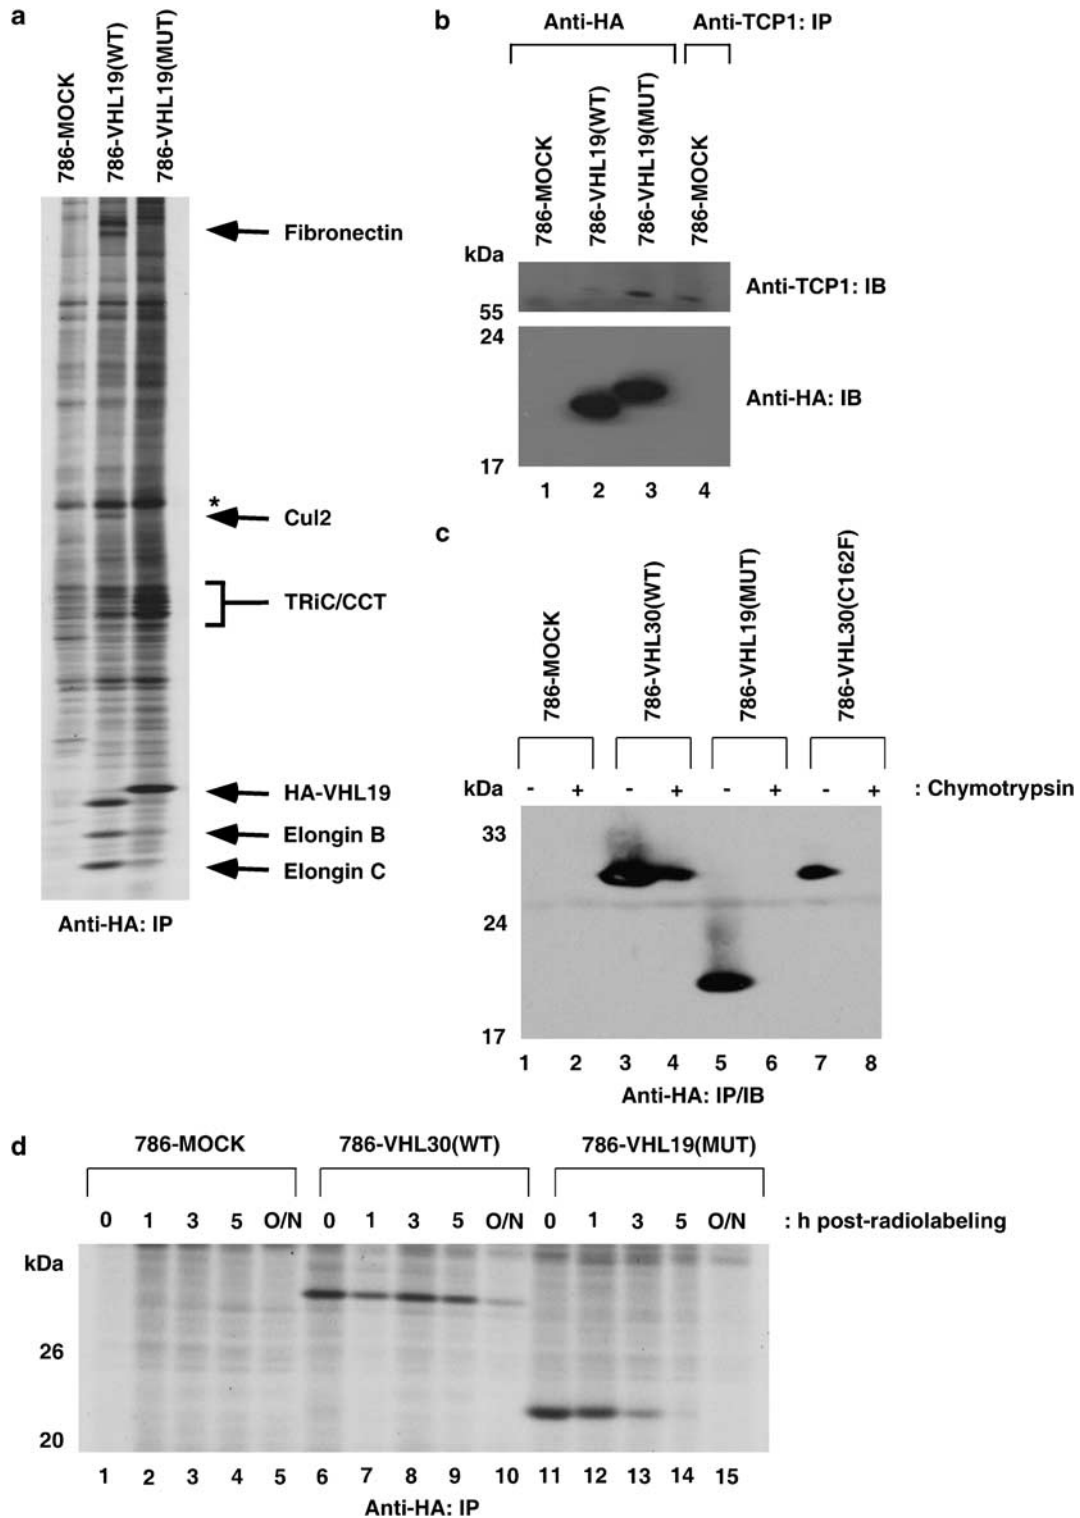

As predicted from the biochemical analysis, stable expression of HA-VHL19(MUT) failed to suppress the tumor growth of 786-VHL19(MUT) cells in SCID mice (Figure 3a). *VHL-null* 786-MOCK subclones grew tumors, whereas 786-VHL30(WT) cells did not form tumors, as expected (Figure 3a). The tumors were resected from the hind legs of mice, fixed in 10% neutral buffered formalin and embedded in paraffin. Sections (5 μ m) were placed on coated slides for standard H&E staining (Figure 3b, first panel). Both the 786-MOCK and 786-VHL19(MUT) tumors were characterized by nests and clusters of cells surrounded by a delicate microvascular network. This feature is characteristic of CC-RCC.³¹ The tumor cells in both xenografts had large, moderately pleomorphic nuclei with prominent nucleoli and variable amounts of pale eosinophilic cytoplasm. The nuclear features are consistent with those seen in high-grade (Fuhrman grade 3–4) RCC. They also contained foci in which the tumor cell nuclei adopted a spindleform morphology, indicative of sarcomatoid differentiation. 786-VHL19(MUT) tumors also stained positive for HA as predicted, indicating the presence of HA-VHL19(MUT) in tumor cells (Figure 3b, second panel), and both tumor types stained for GLUT1 expression (Figure 3b, third panel), which indicates a failure in the negative regulation of HIF in the *VHL-null* or VHL19 mutant cells.

In an effort to determine the affect of mutations in VHL19 on E-cadherin subcellular localization, 786-MOCK and 786-VHL19(MUT) xenografts were stained with an anti-E-cadherin antibody specific to the C-terminus or N-terminus of E-cadherin (Figure 3b, fourth panel or fifth panel,

Figure 2 VHL19 mutant exhibits biochemical signature of a disease-prone mutation. **(a)** The indicated 786-O subclones were radiolabeled with [³⁵S]methionine, lysed and immunoprecipitated with anti-HA antibody. The bound proteins were resolved on SDS-PAGE and visualized by autoradiography. **(b)** The indicated 786-O subclones were lysed and immunoprecipitated with anti-HA antibody (lanes 1–3) or anti-TCP1 antibody (lane 4), and immunoblotted with an anti-TCP1 antibody (upper panel) or anti-HA antibody (lower panel). **(c)** The indicated 786-O subclones were lysed and treated with 10 μ g/ml chymotrypsin for 10 min on ice. Reactions were stopped with 1 mM PMSF and the lysates were immunoprecipitated with an anti-HA antibody. Bound proteins were resolved by SDS-PAGE and immunoblotted with an anti-HA antibody. **(d)** The indicated 786-O subclones were pulsed with [³⁵S]methionine for 1 h, chased for the indicated times and then cell lysates were immunoprecipitated with an anti-HA antibody. Bound proteins were resolved by SDS-PAGE and visualized by autoradiography. Experiments were performed multiple times using several subclones with similar outcome. * Represents nonspecific proteins. IP, immunoprecipitation; IB, immunoblot.

respectively). Interestingly, both tumor types did not exhibit membranous E-cadherin but showed nuclear E-cadherin, which was exclusively stained by C-terminus-specific anti-E-cadherin antibody. This is consistent with the C-terminally cleaved nuclear E-cadherin observed in CC-RCC samples on

TMA. However, the nuclear E-cadherin expression in 786-MOCK xenograft is inconsistent with CC-RCC cells with negative VHL status, which correlated with negligible E-cadherin expression with no detectable nuclear E-cadherin staining. Human colon tissue was used as a positive control,

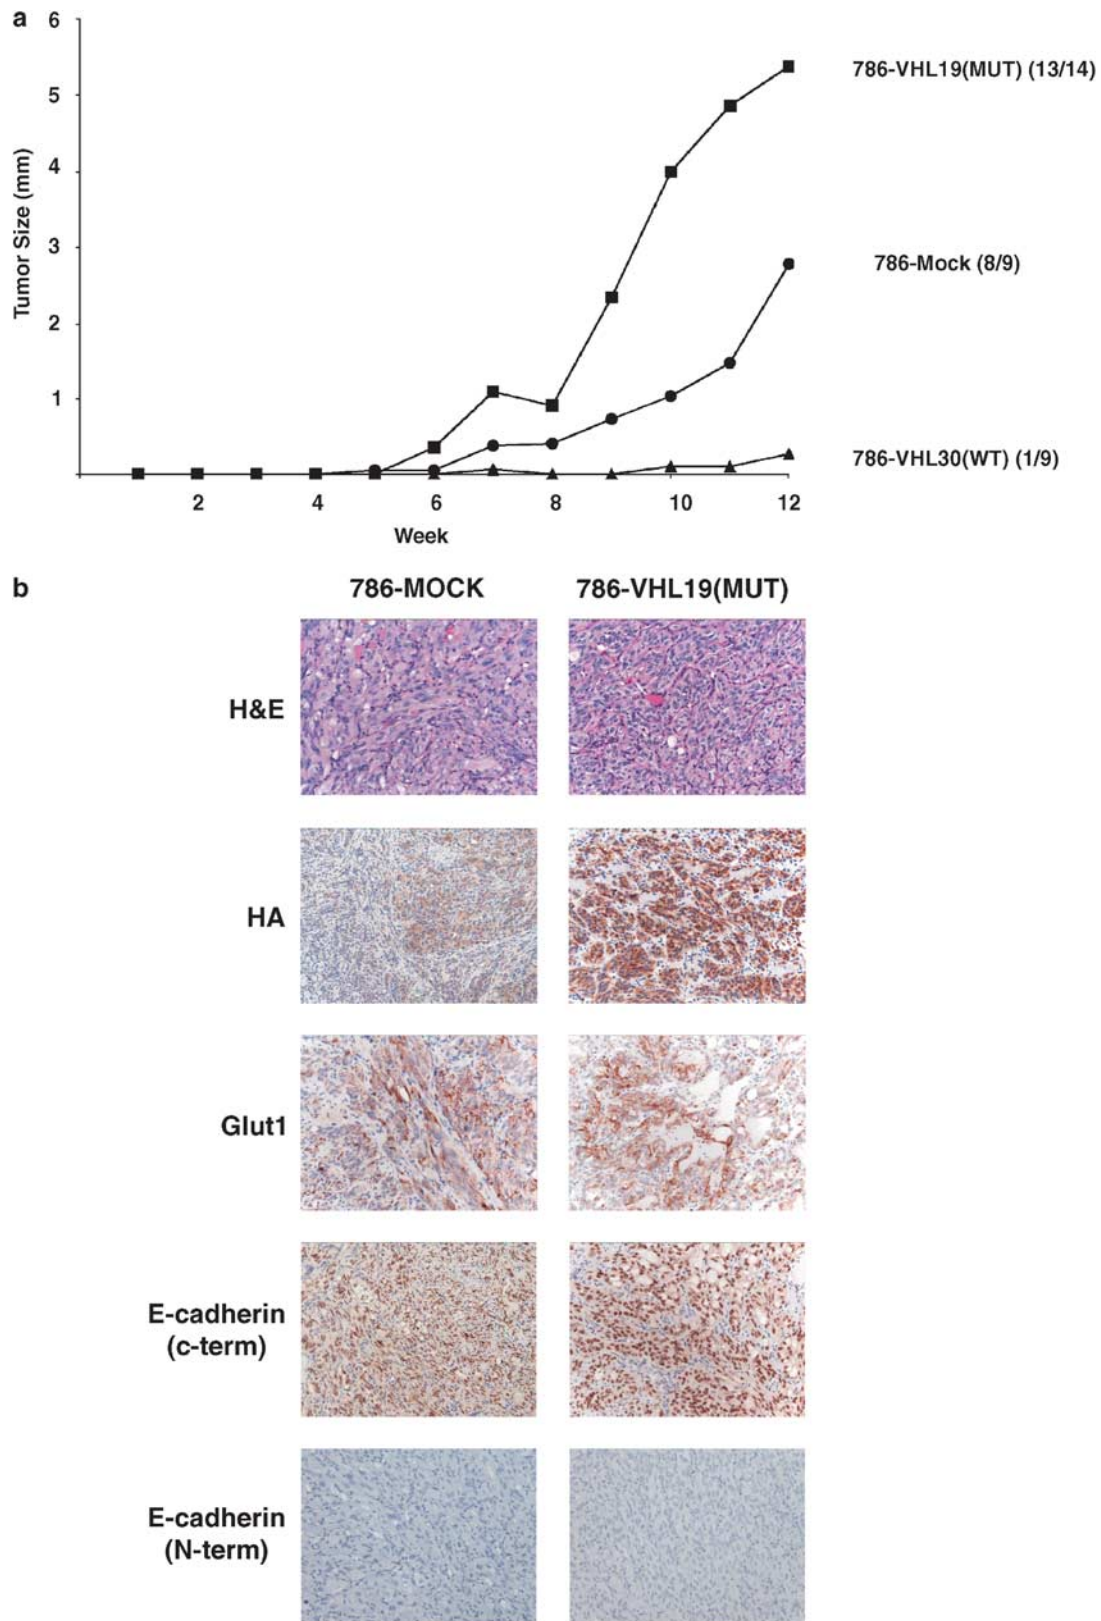

Figure 3 786-MOCK and 786-VHL19(MUT) xenografts in SCID mice display nuclear E-cadherin. **(a)** SCID mice were injected intramuscularly in the left hind leg with the indicated 786-O subclones and tumor size measured over time. The total number of mice that grew tumor is indicated in parentheses. This is a representative experiment of three independent experiments using multiple isogenic clones. **(b)** A representative photomicrographs of 786-MOCK and 786-VHL19(MUT) xenografts fixed and embedded in paraffin for the indicated immunohistochemical analysis. Figure 4 VHL immunoreactivity associates with low-grade tumors and better prognosis. (a) The CC-RCC samples on TMA were categorized as either low grade (Fuhrman grades 1 and 2) or high grade (Fuhrman grades 3 and 4) and scored for VHL and nuclear E-cadherin immunoreactivity. Solid bars represent the percentage of samples with positive nuclear E-cadherin staining. Open bars represent the percentage of samples with negative nuclear E-cadherin staining. Hatch bars represent the percentage of samples with indeterminate nuclear E-cadherin staining. (b) Representative sections from 19 CC-RCC were analyzed according to tumor behavior, based on clinical follow-up information. Good-prognosis cases were selected based on the absence of recurrent disease over 5 years of follow-up. Poor-prognosis cases were selected based on the presence of metastases at the time of presentation or development of metastases within 1 year of nephrectomy. VHL staining (left panel) for these sections was scored semi-quantitatively as being negative (open bars), weak (hatch) or strong (solid bars). Nuclear E-cadherin staining (right panel) was scored as either positive (solid bars) or negative (open bars).

which stained membranous E-cadherin using both E-cadherin antibodies (data not shown).

VHL Immunoreactivity, which Correlates with Nuclear E-Cadherin, is Associated with Low-Grade Tumors and Better Prognosis

Fifty CC-RCC samples on TMA met the quality standard criteria (see Materials and Methods) with regards to VHL immunoreactivity. Tumors were categorized as either low grade (Fuhrman grades 1 and 2) or high grade (Fuhrman grades 3 and 4). A total of 74% (26/35) of low-grade tumors had positive VHL immunoreactivity, in contrast to 47% (7/15) of the high-grade tumors (Figure 4a). In addition, a high percentage (46% or 16/35) of the low-grade tumor samples stained positive for nuclear E-cadherin, whereas only 29% (10/35) were nuclear E-cadherin negative. The remaining 26% (9/35) had uncertain or inconclusive nuclear E-cadherin staining (ie, 2 out of 4 cores stained positive). Furthermore, of the 26 VHL-positive low-grade tumors, 15 exhibited nuclear E-cadherin expression while only four were negative, and the remaining seven were inconclusive of nuclear E-cadherin staining (Figure 4a). In contrast, a majority (67% or 10/15) of the high-grade tumors showed negative

nuclear E-cadherin staining. Five of those 10 were VHL positive and the other five VHL negative (Figure 4a).

In an effort to assess the relationship between VHL immunoreactivity and tumor behavior, we selected representative sections from 19 CC-RCC according to tumor behavior based on clinical follow-up information. Specifically, good prognosis cases were selected based on the absence of recurrent disease over 5 years of follow-up. Poor prognosis cases were selected based on the presence of metastases at the time of presentation or development of metastases within 1 year of nephrectomy. VHL staining for these sections was scored semi-quantitatively as being negative, weak (focal or moderately diffused) or strong. A total of 60% (6/10) of the tumors in the good prognosis group showed strong VHL immunoreactivity, as compared with 22% (2/9) of the tumors from the poor-prognosis group (Figure 4b). Moreover, none of the good-prognosis tumors showed negative VHL staining and 4/10 had weak staining, whereas 67% (6/9) of the poor-prognosis tumors showed only weak expression, including one case that was negative for VHL expression (Figure 4b). Furthermore, 70% (7/10) of good-prognosis tumors had nuclear E-cadherin, whereas only 33% (3/9) of poor-prognosis tumors had E-cadherin localized to the nucleus (Figure 4b). These results suggest that VHL

immunoreactivity and E-cadherin expression/subcellular localization are associated with clinical outcome, such that there is a trend where higher Fuhrman grade or more aggressive CC-RCC have reduced VHL and E-cadherin immunoreactivity. CC-RCC with preserved VHL immunoreactivity, but a VHL mutation, associate with E-cadherin localized to both the membrane and the nucleus, and with low-grade tumors with more favorable clinical behavior.

DISCUSSION

Enhanced ability to predict tumor behavior in patients with CC-RCC will result in better selection of established and novel therapies. In this study we examined 45 patient CC-RCC samples for VHL and E-cadherin immunoreactivity, and 50 samples for Fuhrman grade and VHL immunoreactivity. CC-RCC samples that stain positive for VHL are associated with better prognosis and low Fuhrman grade, whereas CC-RCC samples devoid of VHL expression have worse clinical outcome and high Fuhrman grade. In addition, nuclear localization of E-cadherin is correlated with positive, albeit mutant, VHL immunoreactivity. Therefore, CC-RCC can be subdivided into two groups where the first group is associated with the loss of VHL and E-cadherin expression and likely have poor prognosis. The second subset has positive VHL immunoreactivity correlating with nuclear E-cadherin localization and likely have better prognosis. Despite the positive staining of VHL in this subset, direct DNA sequencing revealed VHL mutations in the vast majority of CC-RCC samples. This is also consistent with the report by Yao *et al*,⁴³ demonstrating that the presence of VHL alteration is associated with better outcome for patients with stage I–III CC-RCC.

Although this is the first report of nuclear E-cadherin in CC-RCC, aberrant staining of E-cadherin in the nucleus has been reported in other types of cancer, including Merkel cell carcinoma, signet ring cell carcinoma, and solid pseudopapillary tumors (SPT) of the pancreas.^{44–46} The cytoplasmic domain of E-cadherin is in a complex with β -catenin, implicating a potential ‘outside-in’ signaling, where a loss of E-cadherin or cleavage of E-cadherin releasing the intracellular fragment of E-cadherin would promote nuclear accumulation of β -catenin to associate with the leukocyte enhancer factor (LEF)/T-cell factor (TCF) to regulate the transcription of cell cycle (eg, cyclin D1) or invasion-related genes (eg, metalloproteinase matrilysin).¹⁴ Interestingly, an increased level of cyclin D1 has been observed in RCC cells devoid of VHL at high cell density.⁴⁷ Whether the nuclear localization of E-cadherin in CC-RCC is associated with increased nuclear β -catenin is currently unknown. Furthermore, gastric and colorectal signet ring cell carcinomas and SPT with nuclear E-cadherin showed increased β -catenin levels in the nucleus.^{44,46} However, an expression of nuclear E-cadherin is not an invariable predictor of nuclear β -catenin, as the nuclear localization of E-cadherin in Merkel

cell carcinoma was not associated with increased nuclear β -catenin expression.⁴⁵

Although the general morphology and the microvasculature of the CC-RCC xenografts in SCID mice were reminiscent of patient CC-RCC, the nuclear features were more like those seen in high grade/sarcomatoid RCC. The apparently aggressive morphologic features seen in these grafts may be a result of repeated subculturing and ‘phenotypic drift’ over time. This phenomenon may well account for the discrepancies observed between the xenografts and patient samples used in our study. Notably, while CC-RCC xenografts in SCID mice recapitulated nuclear E-cadherin expression profile, nuclear E-cadherin staining was also observed in VHL-null CC-RCC xenografts, which is different from human tumor samples where CC-RCC with negative VHL staining lacked E-cadherin expression.

Proper regulation of cell–cell adhesion is crucial for growth, differentiation and development. The deregulation of cell adhesion leading to a disruption in cell anchorage can lead to pathological processes including tumor invasion and metastasis caused by alterations in cell movement and signaling.²¹ E-cadherins are Ca^{2+} -dependent homophilic adhesion molecules that are associated with catenins and are major members of adherens junctions in polarized epithelial cells. E-cadherin has been shown to be regulated by several different mechanisms, including post-translational modification and regulation of gene expression.^{21,48} Proteolytic ectodomain release of transmembrane receptors, such as E-cadherin, is proving to be an important mechanism in regulating signaling functions of the cell surface proteins, resulting in the aberrant cell adhesion and altered intracellular signaling.²¹ Release of the E-cadherin– β -catenin complex from the membrane has previously been shown to result in elimination of cell–cell junctions.⁴⁹ Furthermore, several type I transmembrane molecules have been shown to translocate to the nucleus following cleavage, including Notch, ErbB-4 and γ -protocadherin.^{50–52} For example, the translocation of Notch to the nucleus promotes Notch-mediated activation or repression of target genes through its interaction to transcription factors.⁵³ Although the function of nuclear E-cadherin is unknown, it is possible that like Notch, the E-cadherin cleavage product might influence the transcription of target genes when it localizes to the nucleus.

The soluble cleaved form of E-cadherin has been observed in serum under non-pathological conditions, but increased levels of the soluble form have been detected in patient peripheral blood samples^{24,54} and urine samples⁵⁵ in a variety of diseases.²¹ It has been suggested that the 80-kDa soluble fragment may serve as a useful biomarker of disease progression for a number of cancers, including prostate,²³ gastric,²⁴ hepatocellular²⁴ and bladder cancer.⁵⁵ There has also been a correlation between tumor stage, histological grade and elevated levels of soluble E-cadherin, likely because the detection of soluble E-cadherin has been associated with increased invasiveness.^{23,56,57} Although reasonable, it is

currently unknown whether the detection of the C-terminal fragment of E-cadherin in the nucleus of CC-RCC correlates with increased serum level of soluble N-terminal E-cadherin fragment. Thus, future analysis of serum E-cadherin of CC-RCC patients may prove to be a valuable biomarker for CC-RCC.

Ectodomain shedding of transmembrane proteins is mediated by the action of membrane-associated proteases. The matrix metalloproteases (MMP), cathepsins and kallikreins are proteases reported to cleave E-cadherin within its ectodomain.^{18,21,23,58–62} In addition, hepatocyte growth factor/scatter factor (HGF/SF) expression has been associated with E-cadherin ectodomain shedding and increased invasiveness of cancer cells.⁶³ The protease(s) responsible for E-cadherin cleavage in CC-RCC has not been identified. However, it has been shown that VHL regulates the expression of tissue inhibitors of metalloproteinases (TIMPs) and MMP2 and 9, and their deregulation have been shown to promote branching morphogenesis in cells devoid of functional VHL.⁶⁴ Furthermore, HGF/SF and its receptor c-MET are frequently overexpressed in CC-RCC.^{65–68} Therefore, it would be of interest to determine whether the overexpression of MMP2, MMP9 or HGF/SF is responsible for the cleavage of E-cadherin in CC-RCC.
