The latter has been growing much darker and more conspicuous during the last few months, and it seems very probable that this object may resume a good deal of its former prominence during the opposition of 1886. With my 10-inch reflector, power 252, I recorded the spot as passing the central meridian of Jupiter on June 26, 1885, at 7h. 59m., and to-night, June 28, at 9h. 37m. A comparison of these times with the earliest I obtained during the present apparition (1884, September 21, 18h. 28m.) shows that in the interim of 279d. 15h. 9m. the spot has completed 676 rotations with a mean period of 9h. 55m. 39^{os}., which is almost identical with the periods found during the two previous oppositions—viz. 9h. 55m. 39^{is}. But I am hoping to obtain another observation of the spot before the planet leaves us for the season.

Occurrence of "*Torpedo marmorata*" off the Coast of Cornwall

AMONG the fishes included in the British fauna, but whose title to this designation has been considered but doubtfully proved, is the *Torpedo marmorata*, or a form having the spiracles fringed at their edges. It is true that Pennant figures this species, but he omits to mention whether his example was from the British seas or brought from the French coast by Walsh; and subsequent authors on ichthyology are not sufficiently precise in their descriptions to enable one to judge of which form they are adverting to. All the specimens which I have seen in the various British museums have been of the cramp fish, with smooth-edged spiracles, *T. nobiliana*. On June 26 an example of *T. marmorata* was trawled in Mevagissey Bay, and obtained by Mr. Matthias Dunn, who most kindly sent it at once to me, and it arrived at Cheltenham on the evening of the 27th. It was a female, quite fresh, and weighed 3 lb. 10 oz.; its length was 17½ inches, and its breadth across the disk 12 inches. It contained two ova in an early stage of development.

Composite Portraits

It is always desirable to guard new discoveries and inventions by explicit investigation of the nature of the facts discovered and the mode of action of the invention.

The system of composite portraits ingeniously invented by Mr. Galton rightly attracts much attention, and those who have had their interest excited by Mr. Galton's curious portraits of thieves, ruffians, and consumptives, will be interested further by the portrait of American scientific men in NATURE, vol. xxxii. p. 176.

But in using this system as an instrument of discovery it must not be hastily assumed that by its means true averages are secured. At least, they cannot be averages in every respect. Take, for example, the hair. The outer limit is determined by the greatest extent to which the hair has spread outwards on the plate in a number of sitters sufficient visibly to affect it—say three or four. But the inner limit is, in the same way, determined by the limit in the three or four in whom it stretched farthest in. Thus the result must be to give far more than the average amount of hair when the portrait is compounded from a great number of sitters.

As regards the nose, the eyes being the fixed starting-points, the root of the nose will be nearly a fixed point in the photograph; but the tip is limited by shading, and three or four short noses will be sufficient to determine where the tip is to be.

Again, the eyes being fixed points marked on the ground glass of the camera, and breadth between the eyes being different in different persons, it follows that those who have the eyes near together will be photographed on a larger scale than the rest. This enlargement will broaden the composite result. But the tip of the nose, like the tips of the really long noses, will be lost in the dark upper lips of others.

Proof that I am to an important extent correct in these remarks is to be found in your page of American portraits. They present a very remarkable non-American appearance about the nostrils, a vertical elongation accounted for by what I have pointed out. Also the ears are large and vague, the position of the ear relatively to the eye being variable; and there is a more than average breadth of face in three out of the four portraits.

I do not wish to detract from the value of these portraits, rightly understood, but assuredly they give prominence to certain

types of face when these are mixed with others—namely, to broad faces with short noses, long lips, large ears, and a superabundance of hair—and it may be useful that attention be attracted to this.

It will be seen that composite portraiture is not suitable for anatomical objects whose generic characters are to be recorded in explicit statement. But for that and many other purposes, a trustworthy though more laborious and less elegant substitute may be found by determining the mean positions of a number of fixed points in figures accurately obtained.

JOHN CLELAND

Ocular Images and After-Images

MR. NEWALL'S experiment with the glowing match I have been in the habit of performing with my cigar or cigarette, and I have become familiar with the lurid ghost he describes, but the point that first interested me is one not mentioned in his letter, and has reference to the primary serpentine image. This I find to consist of a dark red head and a bright yellowish-red body—the light viewed at rest being of a mean tint, as if, owing to difference in rate of telegraphy, it underwent a process of analysis in its movement over the retina.

I have paid considerable attention to the dying phases of powerful retinal impressions, such as result from too bold a gaze at the sun or his vicar, the paraffin lamp, and am convinced that there is more to record than a mere fading away of a patch of colour. On careful scrutiny the patch is seen to be bordered with a series of coloured bands, which each in turn overspreads it; the order of succession being, unlike that of the primary image in the above experiment, towards the red.

I submit this for confirmation, being conscious that the region of these observations is so largely dominated by memory and imagination as to render it difficult at times to distinguish the psychical from the physiological.

A Query as to Swallows

DURING a recent stay in Suffolk I found a belief prevalent there that swallows lay in necessary stores for their autumn migration by packing small flies under the feathers beneath the wings. My informant told me that he had shot a swallow once in order to ascertain whether this was actually the case; and that he had, as he expected, found many small flies beneath the down. Knowing how liable swallows are to parasitic invasions, I asked of what kind the flies were, and was told "Little gnats, and such like." Is this opinion to be found elsewhere, and is there any ground for it?

THE COMPOUND LOCOMOTIVE

VERY soon after the compound working of steam in marine and stationary engines became an accomplished fact, and the great saving of fuel thereby was apparent, the question of applying the compound principle to the locomotive attracted the attention of the locomotive engineers of this and other countries. At first it was received with very little favour, which is evident even at the present time, there being only two locomotive engineers in this country who are now either trying it experimentally or have it permanently in use on the lines under their control. This has been mostly caused by the idea that the additional gear necessary for the compound working with two or more cylinders would render the engines more liable to break down. Again it was thought, with very good reason, that such engines would have great difficulty at starting, for the reason that during the first revolution of the driving wheels all the power necessary to start the engine would have to be generated in the high-pressure cylinder. This difficulty was soon surmounted in engines fitted with only two cylinders working compound, by the addition of an arrangement by which the engine could be worked as an ordinary locomotive at the commencement, and when fairly started the compound arrangement could then be applied.

The usual arrangement adopted in the early trials of compound locomotives consisted of two outside cylinders of different sizes; the steam having passed through the
