

In reply to the letter in NATURE of May 29 (p. 319) under the heading "Artificial Hiss," the following is a suggestion which may be an answer to the question, though not a practical solution to the problem.

A loud hissing noise accompanies the passing of an electric arc across the gap in such a lamp as is used for optical lanterns, &c. Though this hissing noise does as a rule last for only a short time, yet it appears to me quite a simple matter to regulate the carbons so as to prolong the sound. The actual "hiss" sounds much more of a sibilant than an *f*, such as is produced by a current of air or steam being forced under pressure through a small opening.

Red Water.

IN NATURE of April 4, 1912, Messrs. Mackenzie and Finlay wrote relative to the cause of the occurrence of colouring matter in a sample of water from a crater lake in Uganda, and subsequently in the issues of April 11 and June 6 Messrs. H. Warth and C. Crossland respectively wrote describing the occurrence of similar characteristics in the great salt lake of Sambhar, in Rajputana, also pools at Suez, and near the Rawaya salt lake.

Dr. Gavin McCallum, in a paper read at a meeting of the Geelong Field Naturalists' Club, in March, 1911, entitled "Forms of Life at the Salt-pans," directed attention to this coloration of the water and its blood-red appearance, and described it as being not due to the "colour of the liquid itself, but to the presence in enormous numbers of uniform small round cells. Dr. McCallum also mentions another form as being oval in shape with two cilia or lashes at the narrower end," the cilia and a small portion at the narrower end being colourless. At various times samples of the "red water" have been collected, and kept constantly under microscopical examination both by Dr. McCallum and myself, with the result that we can say the colouring is wholly due to a flagellate organism not unlike *Polytoma uella*, Müll, as figured in the last edition of the "Encyclopædia Britannica," but as this is given as being a species of *Chlamydomonadidæ* in the article on Flagellata, and as a similar genus appears in the article on algæ by a different writer, some confusion evidently exists as to both these orders.

The oval form, as mentioned by Dr. McCallum, has two flagella, about one-third longer than the body, which appear to arise from a sort of collar or circular opening at the anterior end; there are two contractile vacuoles near the base of the flagella, and an eyepot; except the flagella and a small portion at the anterior end, the whole organism is so deeply pigmented with red matter that it is difficult to determine its constituent parts. There are other features, but these it is at present premature to mention. The globular form appears as the brine reaches saturation point, and is a sort of resting stage conditioned by the salinity of the medium in which it lives; this form gives rise to zoospores.

Associated with the flagellate organism is an interesting crustacean, the brine shrimp, very similar to *Artemia salina*, but in all the articles dealing with this crustacean the female is said to carry the eggs underneath the tail, whereas in this shrimp they are carried in sacs on either side, like the egg sacs of the Cyclops. The male, which is much larger than the female, has the usual claspers for holding the female. Dr. McCallum mentions in his article that at 7° to 8° Baume the shrimp sickens and dies; at this stage it becomes the host of the flagellate organism, which absorbs the decaying organic matter in the

interior of the shrimp's body, leaving an absolutely hyaline cast skin.

I may mention that during this period of the organism's existence it is nearly always green, the red matter only making its appearance at a later stage. As the brine reaches crystallisation the ensuing salt is of a reddish hue, due, of course, to the pigmented organism, and it is a matter of conjecture as to whether or no each spherical monad does not form the nucleus of each crystal of salt. The salt, upon exposure to the sun, bleaches, but the zoospores contained within the spherical or globular membrane retain their vitality and issue forth in countless numbers of infinitely small green, actively moving flagellate organisms, upon redissolving the salt.

Phreatoicus in South Africa.

AT the beginning of this month I found some isopods in one of the swift-running streams on the top of Table Mountain; they were quite common in and under the moss covering the stones in the bed of the stream, and were very sluggish. On examination they prove to belong to the family Phreatoicidæ. The occurrence in South Africa of a member of this peculiar family, which hitherto has been recorded only from New Zealand, Australia, and Tasmania, is of great interest as bearing on the question of the ancient land connection between the southern continents.

It is a new species, and will shortly be described in the Annals of the South African Museum.

GEOGRAPHY AND TRAVEL.¹

(1) THIS work has originated in the desire of its author to make some public statement of indebtedness. It is, as it were, a memorial laid upon an altar. Dr. Cornish, in his researches, has dealt with phenomena that are cosmic rather than humane; yet we now perceive them set against a background, old as that of the cave-dwellers, where accomplishment is due to the fact that man does not live his life alone. Whether their vessel is rolling fifty-six degrees in the Bay of Biscay, or nearing Ceylon in incense-laden air, whether they are walking in the symbolic garden of the Shogun, or in the shattered streets of Kingston, the essential feature is that the travellers are together. The form adopted as a title merely adds emphasis to this impression.

Except for the stirring adventure of the Jamaican earthquake of 1907, these travellers saw little that others have not seen and liberally described. But what they saw they realised as trained observers. "The greatest astronomical
