Dysfunctional neurotransmission within striatal networks is believed to underlie the pathophysiology of several neurological and psychiatric disorders. Nitric oxide (NO)-producing interneurons have been shown to play a critical role in modulating striatal synaptic transmission. These interneurons receive synaptic contacts from midbrain dopamine (DA) neurons and may be regulated by DA receptor activation. In the current study, striatal NO efflux was measured in anesthetized male rats using an NO-selective electrochemical microsensor and the role of DA in modulating NO synthase (NOS) activity was assessed during electrical or chemical (bicuculline) stimulation of the substantia nigra (SN). Electrical stimuli were patterned to approximate the natural single spike or burst firing activity of midbrain DA neurons. Electrical stimulation of the SN at low frequencies induced modest increases in striatal NO efflux. In contrast, train stimulation of the SN robustly increased NO efflux in a stimulus intensity-dependent manner. NO efflux evoked by SN stimulation was similar in chloral hydrate- and urethane-anesthetized rats. The facilitatory effect of train stimulation on striatal NO efflux was transient and attenuated by systemic administration of the neuronal NOS inhibitor 7-nitroindazole and the nonselective NOS inhibitor methylene blue. Moreover, the increase in NO efflux observed during chemical and train stimulation of the SN was attenuated following systemic administration of the DA D_{1/5} receptor antagonist SCH 23390. SCH 23390 also blocked NO efflux induced by systemic administration of the D_{1/5} agonist SKF 81297. These results indicate that neuronal NOS is activated *in vivo* by nigrostriatal DA cell burst firing via a DA D_{1/5}-like receptor-dependent mechanism.

INTRODUCTION

Nitric oxide (NO) is an unstable free radical gas that functions as a neuromodulator in the central and peripheral nervous system (Boehning and Snyder, 2003). NO diffuses freely across cell membranes and modulates neurotransmission via its influence on target proteins in both pre- and postsynaptic elements. NO is synthesized from L-arginine in a reaction catalyzed by NO synthase (NOS) (Stuehr *et al*, 1991). Three isoforms of this enzyme have been purified, cloned, and sequenced: neuronal NOS (nNOS), inducible NOS (iNOS), and endothelial NOS (eNOS) (Nathan and Xie, 1994). In the striatum, NO is generated primarily via activation of nNOS which is localized to a subclass of

medium aspiny interneurons known to synthesize neuropeptide Y, somatostatin, and GABA (Bredt *et al*, 1990, 1991; Dawson *et al*, 1991; Kubota *et al*, 1993; Vincent, 1994). Considerable evidence has accumulated indicating that striatal NOS interneurons play a critical role in the integration of glutamatergic and dopaminergic neurotransmission within striatal neural networks (for a review, see Calabresi *et al*, 2000a; West *et al*, 2002).

Striatal nNOS interneurons receive synaptic contacts from the frontal cortex (Vuillet *et al*, 1989; Salin *et al*, 1990) and are activated by corticostriatal synaptic transmission (Kawaguchi, 1993; Berretta *et al*, 1997). Robust glutamatergic transmission is thought to activate striatal nNOS and NO signaling largely via the stimulation of NMDA receptors (Marin *et al*, 1992; East *et al*, 1996; Iravani *et al*, 1998; Crespi *et al*, 2001; Crespi and Rossetti, 2004), although other glutamatergic receptors may also be involved (Marin *et al*, 1992, 1993; Kendrick *et al*, 1996; Nishi *et al*, 2005). Evidence also exists indicating that activation of intrinsic cholinergic neurons may stimulate striatal nNOS activity via a muscarinic receptor-dependent

mechanism (O'Shaughnessy and Bhoola, 1986; Consolo et al, 1999).

In addition to their glutamatergic inputs, nNOS interneurons have been shown to be heavily innervated by tyrosine hydroxylase (TH) immunoreactive fibers (Fujiyama and Masuko, 1996; Hidaka and Totterdell, 2001). Early *in situ* hybridization studies indicated that NOS interneurons contain low levels of dopamine (DA) D₁-like receptor mRNA (Le Moine et al, 1991). Moreover, recent double-labeling immunocytochemical studies have shown that the majority of striatal NOS/somatostatin-immunoreactive interneurons specifically localize D₅ receptors (Rivera et al, 2002). Additionally, the firing activity of electrophysiologically identified NOS interneurons is strongly enhanced by D_{1/5} DA receptor activation (Centonze et al, 2002). Given the proximity of glutamatergic and dopaminergic inputs on the NOS interneuron dendrites (Fujiyama and Masuko, 1996; Hidaka and Totterdell, 2001), it is likely that these afferents interact via presynaptic and/or postsynaptic mechanisms to regulate striatal NOS activity. This is supported by histochemical evidence that both NMDA and D_{1/5} receptor antagonists decrease NOS activity measured *ex vivo* (Morris et al, 1997). Interestingly, D_{1/5} receptor activation increases striatal tissue levels of the NO second messenger cGMP via an unknown mechanism (Altar et al, 1990). Given that striatal medium spiny neurons (MSNs) have been shown to contain high levels of guanylyl cyclase (GC) and other proteins associated with cGMP signal transduction pathways (Ariano, 1983), it is plausible that the increase in striatal cGMP levels observed by Altar et al following D_{1/5} agonist administration was an indirect effect of dopaminergic influences on the activity of nNOS-containing interneurons. Taken together, these studies indicate that DA neurotransmission may stimulate NOS neuron activity and striatal NO signaling directly via D_{1/5} receptor activation.

Considerable evidence exists indicating a role for NO-DA interactions in the generation of normal locomotor behavior and in pathophysiological conditions such as Parkinson's disease (PD) and drug abuse. Thus, behavioral studies have demonstrated that pharmacological blockade of NO signaling decreases basal locomotor activity (Stewart et al, 1994) and behaviors induced by substance P (Mancuso et al, 1994), D₁ and D₂ agonists (Starr and Starr, 1995), NMDA receptor antagonists (Deutsch et al, 1996), and a variety of abused drugs (see below). Interestingly, multiple measures of striatal NOS activity are depressed in 6-OHDA-lesioned animals (de Vente et al, 2000; Sancesario et al, 2004) and patients with PD (Bockelmann et al, 1994; Eve et al, 1998), indicating that agents designed to target nitrergic signaling may be useful for the treatment of movement disorders.

In order to further characterize the interaction between dopaminergic and nitrergic transmission in the rat striatum, the current study examined the impact of electrical and chemical stimulation of the substantia nigra (SN) on NO efflux measured *in vivo* using an NO-selective electrochemical microsensor (Zhang, 2004). To our knowledge, the current study is the first to utilize NO microsensor recordings to examine the role of nigrostriatal pathways and DA receptor activation in regulating striatal NO synthesis in the intact animal.

MATERIALS AND METHODS

Drugs

Chloral hydrate, urethane, R-(+)-SCH 23390 HCl (SCH 23390), R-(+)-SKF 81297 HBr (SKF 81297), 7-nitroindazole (7-NI), (-)-bicuculline methiodide (BIC), and Cremophor EL were purchased from Sigma (St Louis, MO). (±)S-Nitroso-N-acetyl-penicillamine (SNAP) used for calibration of NO electrodes was obtained from World Precision Instruments (WPI, Sarasota, FL). Methylene blue (MB) was purchased from Fisher Scientific (Hanover Park, IL). All other reagents were of the highest grade commercially available.

Subjects and Surgery

Electrochemical measurements were made from male Sprague-Dawley (Harlan, Indianapolis, IN) rats weighing 245–400 g. Prior to experimentation, animals were housed two per cage under conditions of constant temperature (21–23°C) and maintained on a 12:12 h light/dark cycle with food and water available *ad libitum*. All animal procedures were approved by the Chicago Medical School Institutional Animal Care and Use Committee and adhere to the *Guide for the Care and Use of Laboratory Animals* published by the USPHS. Prior to surgery, animals were deeply anesthetized with chloral hydrate (400 mg/kg) or urethane (1.5 g/kg) and placed in a stereotaxic apparatus (Narashige International USA Inc., East Meadow, NY) so that the skull was set in a horizontal plane. After drilling a burr hole (~2–3 mm in diameter) in the skull overlying the dorsal striatum (coordinates: –0.5 to 2.0 mm anterior from bregma, 2.0–3.5 mm lateral from the midline), the dura was resected and the microsensor or microdialysis probe was lowered into the striatum using a Narishige micro-manipulator. All coordinates were derived from a rat brain stereotaxic atlas (Paxinos and Watson, 1986). The level of anesthesia was periodically verified via the hind limb compression reflex and maintained using supplemental administration of anesthesia as previously described (Floresco and Grace, 2003; West and Grace, 2004). Temperature was monitored using a rectal probe and maintained at 37–38°C with a heating pad (Fintronics Inc, Orange, CT).

Electrical Stimulation

In each experiment, twisted-pair bipolar stimulating electrodes (Plastics One, Roanoke, VA) were implanted into the SN (coordinates: 3.0–4.2 mm anterior to lambda, 1.5–2.0 mm lateral to midline, 7.5–8.5 mm ventral to the brain surface) ipsilateral to the microsensor/dialysis probe. Electrical stimuli with durations of 500 µs and intensities between 0.5 and 1.0 mA were generated using a Grass stimulator (S88) and photoelectric constant current/stimulus isolation unit (PSIU6F, Grass Instruments, Quincy, MA) and delivered in single pulses (2 Hz) or as stimulus trains (20 Hz, 800 ms train duration, 5 s intertrain interval (ITI)) for a duration of 100 s. These stimulation parameters were derived from the studies of Hyland et al (2002) and were designed to approximate the natural burst firing (spikes per

burst, intraburst frequency, and bursts per second) of high bursting DA neurons recorded in freely moving animals.

In Vivo Microdialysis

Concentric microdialysis probes (Bioanalytical Systems, West Lafayette, IN) having 3–4 mm of exposed membrane (225 μ m diameter, 6000 d permeability) were implanted into the dorsal striatum (coordinates: 0.7 mm anterior to bregma, 3.0 mm lateral to midline, 6.5 mm ventral to brain surface) using a Narashige micromanipulator (West and Grace, 2002). Following implantation, probes were perfused with artificial CSF (aCSF) containing (in mM) 145 NaCl, 2.7 KCl, 1.0 MgCl₂, 1.2 CaCl₂, 2.0 NaH₂PO₄, and 2.0 Na₂HPO₄ at a rate of 2 μ L/min using a BAS microperfusion pump (Bioanalytical Systems, West Lafayette, IN). Microdialysis samples were collected every 10 min (represents one fraction) into 10 μ L of HPLC mobile phase to minimize degradation of DA and immediately analyzed by HPLC-EC (ESA, Inc., Chelmsford, MA) (Floresco *et al*, 2003). The HPLC system mobile phase consisted of 75 mM sodium phosphate buffer (pH = 5.6), 25 μ M EDTA, 0.87 mM SDS ion pairing reagent, 12.5% methanol, and 15% acetonitrile. The mobile phase flow rate was 1.0 ml/min. DA was detected using an ESA Coulochem II detector equipped with a guard cell (+300 mV) and a dual-electrode analytical cell (ESA 5014; E1 = -175 mV, E2 = +175 mV). The HPLC system was calibrated using external standards (detection limit of dialysate DA, ~2 fmol).

Electrochemical Detection of Nitric Oxide

Striatal NO levels were determined using an NO selective, amperometric microsensor (Zhang, 2004; ISO-NOPF200, WPI, Sarasota, FL). The NO oxidation current (electrode potential of 0.85 V against a built in Ag/AgCl reference electrode) was detected using a commercially available amplifier (Apollo 4000, WPI) and recorded using software applications (WPI) running on an IntelTM-based microcomputer with a data acquisition board interface (WPI). Prior to each experiment, the electrode was calibrated (Figure 1) in a temperature-controlled chamber (Diamond Instruments) using known solutions of NO generating compounds (Ohta *et al*, 1997; Zhang, 2004). Calibration curves were routinely constructed in order to determine the sensitivity of the electrode and confirm that the NO oxidation current exhibited a linear response to NO concentrations ranging from 0.6 to 48 nM (Figure 1, inset). The selectivity of the NO microsensor for NO was also confirmed on occasion *in vitro* using known concentrations of DA and all other drugs ($\leq 1 \mu$ M) utilized in the current study.

Drug Preparation and Administration

Chloral hydrate, urethane, SCH 23390, SKF 81297, MB, and BIC were dissolved in physiological saline (0.9%). 7-NI was dissolved in a 10% solution of Cremophor EL in saline (0.9%) solution (Eblen *et al*, 1996). The effective dose of 7-NI was derived from the ED₅₀ described by Kalisch *et al* (1996) (25 mg/12.5 ml/kg, i.p.). In studies using MB, the dose of 10 mg/kg was derived from the range of doses used in previous studies (Volke *et al*, 1999; Harvey and Bester, 2000;

Figure 1 Calibration of the nitric oxide microsensor *in vitro*. Prior to implantation, electrodes were calibrated in a temperature-controlled (37°C) chamber containing copper sulfate solution (0.1 M). NO microsensor calibration curves (inset) were constructed from the NO oxidation current measurements generated from known concentrations of the NO donor *S*-nitroso-*N*-acetyl-penicillamine (SNAP, 100 μ M) yielding NO concentrations of 0.6–48 nM as indicated by arrows. Electrode sensitivity to exogenous NO (pA/nM NO) was derived from the slope of the regression line.

Wegener *et al*, 2000). The NO microelectrode response to SN stimulation was tested on average 2–3 times prior to drug administration, with stimulations separated by 15–30 min from each other in order to obtain 2–3 consecutive responses that did not vary by >20%. The average of these measures was considered as the control response to which responses following drug administration were compared. Effective doses of SCH 23390 (100, 500 μ g/kg, i.p.) and SKF 81297 (50 μ g/ml/kg, i.v) were derived from the range previously reported in the literature (Gonon, 1997; Morris *et al*, 1997; Reynolds *et al*, 2001; Floresco and Grace, 2003; Brady and O'Donnell, 2004). In studies using SKF 81297, drug was administered intravenously (via a lateral tail vein) after obtaining 150 s of basal activity. In these studies, the response to SKF 81297 was recorded for 20–30 min, during which NO oxidation current levels generally returned towards baseline. In some experiments, SCH 23390 was administered systemically (i.p.) as described above, and the impact of SKF 81297 on NO efflux was reassessed approximately 20 min later. No electrical stimulation was applied during the drug testing phase. BIC was administered via a 25G cannula, implanted into the midbrain with the tip targeted just dorsal to the SN, utilizing a BAS MD-1001 syringe drive system (Bioanalytical Systems, West Lafayette, IN). A total of 200 ng/ μ L of BIC/saline was administered over 2 min at a rate of 0.5 μ L/min. In some experiments, SCH 23390 (500 μ g/kg i.p.) was administered approximately 20 min prior to the BIC injection.

Histology

Following experimentation, animals were deeply anesthetized and perfused transcardially with ice-cold saline followed by 10% formalin in buffered phosphate (PB) (EMS, Hatfield, PA). Brains were then removed and postfixed in 10% formalin/PB for at least 1 week. Next, brains were immersed in PBS/sucrose solution (30%) until

saturated and sectioned into 50 μm coronal slices, mounted, and stained with Neutral red/Cresyl Violet (10:1) solution to enable histological determination of stimulating electrode and NO sensor or dialysis probe sites (Figure 2a, b).

Data Analysis

In microdialysis studies, chromatograph peak heights (cm) corresponding to both standards and dialysate-derived DA were converted into fmol/ μl values using a spreadsheet program (Floresco et al, 2003). HPLC-EC calibration (nA/ng) for a given analyte was determined daily by injecting 100–200 pg of standard onto the HPLC (ESA, Inc., Chelmsford, MA). The average of the three stable fractions immediately preceding the experimental manipulation and

not varying by >20% in analyte concentration (fmol/ μl) was defined as the control (100%). Following baseline determination, electrical stimulation was performed for one fraction and DA levels were monitored for 20–30 min poststimulation. Data are expressed as percent of control (not corrected for *in vitro* probe recovery).

In experiments using NO microsensors, the NO oxidation current (pA) was allowed to stabilize for at least 150 s prior to stimulation. The NO oxidation current recorded (50 Hz sampling frequency) during the last 30 s of the prestimulation period was then averaged using Apollo 4000 software applications (WPI) and subtracted from the mean NO oxidation current recorded during the last 30 s of the stimulation period. In experiments where SKF 81297 was administered systemically, the NO oxidation current was measured as the average of a 100 s period recorded 150 s after the start of SKF 81297 injection, minus the average of the last 30 s recorded prior to the injection of the drug. Using these methods, the peak increase in NO oxidation current was consistently measured across animals in an unbiased manner. Data are expressed as concentration NO (nM) as determined from *in vitro* calibration curves. The statistical significance of drug- and stimulation-induced changes in NO oxidation current was assessed using either an unpaired or paired *t*-test or one/two-way analysis of variance (ANOVA) with repeated measures (RM) as indicated (Sigma Stat, Jandel). Additionally, either Dunnett's multiple comparisons test, Bonferroni, or Tukey *post hoc* tests was used as indicated to determine which group(s) contributed to overall differences seen with ANOVA. Data pertaining to DA and NO efflux are graphically represented as the mean percent of control and nM $\pm$ SEM, respectively.

RESULTS

Electrode, Microdialysis Probe, and Cannula Placements

In experiments involving electrical stimulation of the SN, identified stimulating electrode tips were confirmed to lie within the SN or medial forebrain bundle between 2.96 and 4.7 mm anterior to the interaural line, 1.5 and 3.0 mm lateral to the midline, and 7.5 and 9.0 mm ventral to the surface of the skull (Figure 2b; Paxinos and Watson, 1986). In experiments involving chemical stimulation of the SN, all infusion cannula tips were confirmed to lie within the SN between 3.2 and 4.2 mm anterior to the interaural line, 1.5 and 2.4 mm lateral to the midline, and 7.0 and 7.8 mm ventral to the surface of the skull (Paxinos and Watson, 1986). Identified placements for dialysis probes/NO electrodes implanted into the striatum (Figure 2a) were verified to lie between 0.8 mm posterior and 1.7 mm anterior to bregma, 1.5 and 4.5 mm lateral to the midline, and 3.8 and 7.6 mm ventral to dural surface (Paxinos and Watson, 1986). As the active surface of the NO electrodes ($\sim$ 4–5 mm) and microdialysis probes ($\sim$ 3–4 mm) used in this study was relatively large, it is likely that NO and DA efflux were sampled across several dorsal–ventral striatal sub-regions.

Interestingly, both electrical train (20 Hz) and chemical stimulation (BIC infusions) of the SN were usually observed to induce bilateral whisker twitches (more pronounced on ipsilateral side), which were time-locked to the stimulus

Figure 2 Position of implants in the dorsal striatum and SN. (a) An NO microsensor or microdialysis probe was implanted into the striatum and NO oxidation current or extracellular DA levels were determined prior to, during, and after SN stimulation. (b) A stimulating electrode was implanted into the SN or MFB (see Materials and Methods). The white arrows indicate the recording electrode track in the anterior dorsal striatum (a) and stimulating electrode termination point (b). ac, anterior commissure; SNc, substantia nigra compacta; SNr, substantia nigra pars reticulata; LV, lateral ventricular; CC, corpus callosum; HC, hippocampus; D, dorsal; M, medial.

train or drug infusion. We believe the observed response was specific to stimulation in or proximal to the SN because: (1) electrodes that were not placed in the SN showed a whisker twitch response that was greatly reduced or absent, (2) the same twitching response was observed during chemical stimulation indicating that it was not induced by current spread to the cerebral peduncle or activation of fibers of passage in the midbrain, (3) during chemical stimulation the whisker twitch did not appear immediately, but only after NO levels were observed to rise substantially from baseline, (4) the response disappeared once the NO levels began to approach prestimulation levels. Our qualitative observations correlating stimulus-induced whisker twitch responses with histological assessments of electrode/cannula termination sites indicate that this response is an important and useful sign that the electrode/cannula was accurately implanted in the SN region.

Impact of Electrical Stimulation of the SN on Striatal NO and DA Efflux

To characterize the potential role of DA transmission in modulating striatal NO synthesis, afferents from the SN were activated using electrical stimulation (500–1000 μ A) delivered for 100 s as low frequency single pulses (2 Hz, 0.5 ms), or as trains of high-frequency stimulation patterned to approximate the natural burst firing activity of midbrain DA neurons (20 Hz, 800 ms train duration, 5 s ITI, see Materials and Methods). High-frequency SN stimulation (1000 μ A) significantly increased striatal DA efflux over basal levels by $139 \pm 42\%$ (Figure 3a; $p < 0.05$). The observed stimulation-induced increase in DA efflux typically returned to baseline 10–20 min after cessation of stimulation. Basal striatal extracellular DA levels were 2.40 ± 0.6 fmol/ μ l.

These studies also examined the impact of stimulation amplitude (500, 750, 1000 μ A) on NO efflux evoked during low (2 Hz) and high (20 Hz) frequency stimulation of the SN. The results of these studies indicated that NO efflux evoked during train stimulation (20 Hz) was significantly greater than NO evoked at the same current intensities during low-frequency stimulation (2 Hz) of the SN (Figure 3b,c; $p < 0.05$). The effect of different frequencies of stimulation also depended on the intensity of current delivered. Thus, there was a significant interaction between frequency and current (Figure 3c; $p < 0.05$). Electrical stimulation of the SN at a low frequency (2 Hz) did not affect striatal NO efflux in a current intensity-dependent manner (Figure 3c; $p > 0.05$). In contrast, train stimulation (20 Hz) significantly increased striatal NO efflux at all stimulus intensities examined in an intensity-dependent manner (Figure 3c; $p < 0.05$). NO efflux was significantly higher following train stimulation at 750 and 1000 μ A (Figure 3c; $p < 0.01$, $p < 0.001$) as compared to that evoked at 500 μ A. No significant differences were observed between NO efflux evoked at 750 and 1000 μ A ($p > 0.05$).

Impact of Repeated Stimulation and Anesthesia on NO Release

The facilitatory effect of high-frequency SN stimulation (20 Hz, 800 ms train duration, 5 s ITI, 750 μ A) on striatal NO

Figure 3 High-frequency stimulation of SN robustly increases DA and NO efflux *in vivo*. (a) Dialysate samples were collected every 10 min during the prestimulation (–40 to –10), stimulation 0 (20 Hz, 800 ms train duration, 5 s ITI, 1000 μ A, 0.5 ms pulse duration), and poststimulation periods (10–30). High-frequency SN stimulation significantly increased striatal DA efflux over basal levels ($p < 0.05$, RM-ANOVA with Bonferroni *t*-test, $n = 4$). Basal extracellular DA levels were 2.40 ± 0.6 fmol/ μ l (mean $\pm$ SEM). (b) A representative recording showing the NO oxidation signal during the prestimulation (0–150 s), stimulation (150–250 s), and the poststimulation (250–500 s) periods. (c) High-frequency stimulation (100 s, 20 Hz at 500, 750, 1000 μ A, 0.5 ms, 5 s ITI) significantly increased ($p < 0.001$, two-way ANOVA-RM, $n = 9$) striatal NO efflux over levels evoked during low-frequency (2 Hz) stimulation at the higher current intensities (750–1000 μ A at 20 Hz). The magnitude of NO efflux evoked by SN stimulation (750–1000 μ A, 20 Hz) was significantly greater than that evoked by the lower intensity (500 μ A, 20 Hz) (** $p < 0.01$, *** $p < 0.001$, two-way ANOVA-RM, $n = 9$). Extracellular NO levels following the 2 Hz stimulation were: 0.6 ± 0.8 nM, 2.1 ± 0.8 nM, and 1.3 ± 1.1 nM at 500, 750, and 1000 μ A, respectively. Following train stimulation of the SN, extracellular NO levels were: 3.0 ± 1.5 nM, 7.2 ± 1.2 nM, and 9.7 ± 1.5 nM at 500, 750, and 1000 μ A, respectively. Results are expressed as the mean $\pm$ SEM.

efflux was transient and reproducible over time (15–30 min intervals between S1 and S2 stimulation periods) in animals anesthetized with either chloral hydrate or urethane (Figure 4; $p > 0.05$). Furthermore, the mean magnitude of responses evoked in chloral hydrate (400 mg/kg, i.p.)- and urethane (1.5 g/kg, i.p.)-anesthetized rats was not significantly different (Figure 4, $p > 0.05$).

Systemic Administration of NOS Inhibitors Attenuates the SN Stimulation-Induced Increase in NO Efflux

Systemic administration of vehicle (Cremophor EL in 0.9% Saline, i.p.) alone did not alter the NO response to train stimulation of the SN (Figure 5a,b; $p > 0.05$). Systemic administration of the neuronal NOS inhibitor 7-NI (25 mg/kg, i.p.) attenuated the increase in NO oxidation current evoked during SN train stimulation (Figure 5c,d; $p < 0.01$). These studies indicate that the increase in NO efflux observed during SN stimulation was derived largely from neuronal sources of NO. Systemic administration (~45 min) of the nonspecific NOS inhibitor MB (10 mg/kg, i.p.) also attenuated the NO response associated with SN

Figure 4 Effect of repeated SN stimulation on NO efflux in chloral hydrate- and urethane-anesthetized rats. The increase in NO oxidation signal evoked by train stimulation (750 μ A) of the SN was not significantly different when repeated 15–30 min after the first stimulation trial. Also, no significant differences in NO efflux were observed during SN stimulation in chloral hydrate (S1: 4.7 ± 0.8 nM; S2: 4.8 ± 0.8 nM) compared to urethane (S1: 3.8 ± 0.7 ; S2: 3.9 ± 0.7 nM)-anesthetized rats ($p > 0.05$, two-way RM-ANOVA, chloral hydrate: $n = 20$; urethane: $n = 16$). Results are expressed as the mean $\pm$ SEM.

Figure 5 Systemic administration of a neuronal NOS inhibitor attenuates striatal NO efflux evoked during electrical stimulation of the SN. (a) Representative recording showing the effect of high-frequency stimulation (100 s, 20 Hz, 750 μ A, 0.5 ms) of the SN prior to and following administration of vehicle (10% cremophor EL in 0.9% saline). (b) Vehicle administration did not alter NO efflux (pre-vehicle: 3.7 ± 0.9 nM, post-vehicle: 4.1 ± 1.1 nM; $p > 0.05$, paired t -test, $n = 4$). (c) Representative recording showing the effect of high-frequency stimulation of the SN following (30–60 min) systemic administration of 7-NI (25 mg/kg, i.p.). (d) Striatal NO efflux evoked during SN stimulation was significantly reduced (pre-drug: 8.3 ± 1.0 nM, post-7-NI: 4.2 ± 0.8 ; $**p < 0.01$, paired t -test, $n = 7$) following 7-NI administration. Results are expressed as the mean $\pm$ SEM.

train stimulation (pre-MB: 1.6 ± 0.3 nM; post-MB: 0.5 ± 0.3 nM; $N = 5$, paired t -test, $p < 0.01$). In multiple cases, NO efflux evoked by SN stimulation was observed to return towards pre-MB levels approximately 90 min after the MB injection (data not shown).

Systemic Administration of a D_{1/5} Receptor Antagonist Attenuates NO Efflux Induced by Electrical Stimulation of the SN

In order to examine the potential involvement of DA D_{1/5} receptors in mediating the effects of SN stimulation on striatal NO efflux, SN stimulation was carried out as described above prior to and following (30–60 min) systemic administration of SCH 23390 (100 μ g/kg, i.p.). The increase in NO efflux observed during high-frequency SN stimulation (20 Hz, 800 ms train duration, 5 s ITI; 0.75 mA) was nearly abolished following systemic administration of the DA D_{1/5} receptor antagonist SCH 23390 (Figure 6a,b; $p < 0.05$).

Systemic Administration of a D_{1/5} Receptor Antagonist Attenuates NO Efflux Induced by Chemical Stimulation of the SN

Additional studies were performed using microinjections of BIC (200 ng) into the SN in order to determine the impact of chemical stimulation of this region on striatal NO efflux. These experiments were performed in control rats (no drug treatment) or animals administered SCH 23390 (500 μ g/kg, i.p.) prior to (15–20 min) the intra nigral BIC infusion. In control animals, microinjection of BIC into the SN

Figure 6 Systemic administration of a D_{1/5} receptor antagonist attenuates striatal NO efflux evoked during electrical stimulation of the SN. (a) A representative recording showing the effects of high-frequency stimulation (100 s, 20 Hz, 750 μ A, 0.5 ms) under control conditions and following (30–60 min) systemic administration of SCH 23390 (0.1 mg/kg, i.p.). (b) The mean $\pm$ SEM increase in NO release evoked by train stimulation (750 μ A) was significantly reduced following SCH 23390 treatment (pre-drug: 7.1 ± 2.2 nM; post-SCH 23390: 1.9 ± 0.6 ; $*p < 0.05$, paired t -test, $n = 6$).

produced a robust and sustained increase in striatal NO efflux (Figure 7a, b). In contrast with control animals, subjects pretreated with SCH 23390 exhibited significantly smaller increases in NO efflux following identical intranigral BIC infusions (Figure 7a, b; $p < 0.05$). Intra-nigral administration of vehicle (0.9% saline) did not significantly alter NO oxidation currents (data not shown). These observations are consistent with the above studies using electrical stimulation of the SN and indicate that DA D_{1/5} receptors are critically involved in mediating the effect of SN stimulation on striatal NO efflux.

Impact of DA D_{1/5} Receptor Agonism on Striatal NO Synthesis *In Vivo*

In order to further examine the involvement of D_{1/5} receptor activation in facilitating striatal NO efflux, NO oxidation current was recorded prior to and immediately following systemic administration of the selective D_{1/5} receptor agonist SKF 81297 (50 µg/kg, i.v.). In all animals, the responsiveness of the NO microsensor to high-frequency SN stimulation (20 Hz, 800 ms train duration, 5 s ITI; 0.75 mA) was tested (2–3 separate trials) prior to administration of SKF 81297 in order to verify that the NO microsensor was positioned appropriately in the DA terminal field and confirm the stability of the evoked response (Figure 8a). Systemic administration of SKF 81297 induced a sustained increase in striatal NO efflux (Figure 8a, b). The SKF 81297-induced increase in NO oxidation current lasted

between 12 and 30 min and peaked around 2–4 min from the time of the injection (Figure 8, inset). Moreover, the SKF 81297-induced effect was blocked in the same animals (Figure 8a, b; $p < 0.05$) by systemic administration of the DA D_{1/5} receptor antagonist SCH 23390 (100 µg/kg, i.p.).

DISCUSSION

This study investigated the impact of SN stimulation designed to mimic DA cell burst firing on striatal NO synthesis and the role of DA D_{1/5} receptor activation in mediating this response. A major finding of our study is that NO efflux is stimulated *in vivo* in a frequency- and stimulus intensity-dependent manner following SN train stimulation. Train stimulation also increased striatal extracellular DA levels indicating that this stimulation paradigm was effective in driving the nigrostriatal DA system. Systemic administration of the nNOS inhibitor 7-NI attenuated the SN stimulation-induced increase in NO efflux indicating that the effect was largely dependent on neuronal sources of NO. Furthermore, NO efflux evoked by electrical and chemical SN stimulation was attenuated

Figure 7 Systemic administration of a D_{1/5} receptor antagonist attenuates striatal NO efflux evoked during chemical stimulation of the SN. (a) Two representative recordings showing NO efflux following intranigral administration of bicuculline (BIC, 200 ng/1 µl/2 min) in the absence (left) and presence (right) of the D_{1/5} antagonist SCH 23390 (500 µg/kg i.p.). The black bar underneath traces indicates the period during which BIC was being administered. (b) Systemic administration of the D_{1/5} antagonist SCH 23390 significantly attenuated the NO efflux associated with intranigral administration of the GABA_A antagonist BIC (BIC: 14.5 ± 2.5 nM; SCH 23390 + BIC: 5.0 ± 1.4 nM; $p < 0.05$, unpaired t -test, $n = 5$). Results are expressed as the mean $\pm$ SEM.

Figure 8 Systemic administration of D_{1/5} receptor agonist facilitates NO efflux in the striatum in a manner which is blocked by the administration of D_{1/5} antagonist. (a) A representative recording showing NO efflux following SN train stimulation (—, 100 s, 20 Hz, 750 µA, 0.5 ms), administration of SKF 81297 (—, 50 µg/kg i.v.), and following coadministration of SKF 81297 and SCH 23390 (—, 50 µg/kg i.v. + 100 µg/kg i.p., respectively) in the same animal. The inset depicts the full duration of the same response to SKF 81297. (b) Intravenous administration of the D_{1/5} receptor agonist SKF 81297 induced an increase (1.7 ± 0.4 nM) in NO efflux in the striatum. This increase was blocked following the intraperitoneal administration of the D_{1/5} receptor antagonist SCH 23390 (0.1 ± 0.2 nM; * $p < 0.05$, paired t -test, $n = 5$). S(start) = start of SN stimulation; S(end) = end of SN stimulation. Results are expressed as the mean $\pm$ SEM.

following systemic administration of the D_{1/5} antagonist SCH 23390. When taken together with the observation that systemic administration of the D_{1/5} agonist SKF 81297 increased NO efflux in a manner which was also blocked by SCH 23390 pretreatment, these findings provide strong evidence that phasic DA transmission activates striatal nNOS *in vivo* via a D_{1/5} receptor-dependent mechanism.

Technical Considerations

Since our experiments involved repeated stimulation and were carried out in anesthetized rats, we investigated whether the NO efflux in response to SN stimulation was altered by time and type of anesthesia. The data shown in Figure 4 confirm that the NO oxidation current produced during repeated SN train stimulation is relatively stable over time. Furthermore, the results depicted in Figure 4 indicate that the observed response to SN stimulation was not significantly different in rats anesthetized with chloral hydrate or urethane.

Given that all experiments in the current study were performed in intact animals and all drugs (except BIC) were delivered systemically, it is unclear whether D_{1/5} receptor-mediated activation of NOS activity occurs directly at the level of the striatal NOS interneuron or through an indirect circuit. Since the activation of D_{1/5} receptors stimulates cholinergic interneurons (Aosaki *et al*, 1998) that have reciprocal connections with NOS interneurons (Vuillet *et al*, 1992), the potential role of this and other indirect circuits in the D_{1/5}-mediated facilitation of NOS activity needs to be assessed in future studies. Moreover, high-frequency electrical stimulation of the SN can activate fibers of passage in the midbrain, and potentially, antidromically activate corticospinal neurons which also send axon collaterals to the striatum (Wilson, 2004). Thus, it is conceivable that indirect activation of glutamatergic pathways may have contributed to the effects of SN stimulation on striatal NOS activity. This possibility appears unlikely, however, given our observations that local chemical stimulation of the SN with BIC, which is known to induce burst firing in DA neurons (Tepper *et al*, 1995; Paladini and Tepper, 1999), was also shown to increase striatal NO efflux via a D_{1/5}-mediated mechanism.

Phasic DA Transmission Induces a Robust Increase in Striatal NO Efflux *In Vivo*

The current results indicate that the phasic increase in DA transmission evoked during electrical and chemical stimulation of the SN is particularly effective in facilitating striatal NO release and suggest that information transmitted via the nigrostriatal pathway during DA cell burst firing may be processed and/or amplified by NOS interneurons. Midbrain DA neurons have been shown to exhibit two types of spontaneous discharge patterns: burst and irregular or tonic single spike firing modes (Grace and Bunney, 1984a,b; Tepper *et al*, 1995; Overton and Clark, 1997; Kitai *et al*, 1999). Burst firing has been previously shown to lead to more efficient DA release relative to single pulse stimulation applied at regular intervals (Gonon, 1988). The expression of *c-Fos* has also been shown to be selectively increased by stimuli mimicking natural burst firing, but not by low-

frequency stimulation (Chergui *et al*, 1994, 1996). Interestingly, recordings from behaving animals have shown that burst firing in midbrain DA neurons is associated with salient and motivationally relevant stimuli (Freeman *et al*, 1985; Mirenowicz and Schultz, 1996; Hyland *et al*, 2002). Thus, phasic DA transmission arising during DA cell burst firing is thought to be the mode of DA transmission that mediates rapid, behaviorally relevant signaling across synapses in DA terminal fields (Grace, 1991). In contrast to the phasic DA signal, tonic DA transmission has been described as the pool of DA that is present at steady-state concentrations (5–20 nM) within the extracellular space and is tightly regulated even when the DA system is compromised by 6-OHDA lesions (Grace, 1991). Tonic extracellular DA levels are sustained by DA overflow from synaptic and nonsynaptic sites during corticostriatal glutamate transmission and low-frequency single spike/population activity of midbrain DA cells (Grace, 1991; Floresco *et al*, 2003; West *et al*, 2003). The results of the current study indicate that tonic DA transmission evoked by low-frequency stimulation of the SN results in subtle changes in NO efflux. On the other hand, phasic DA transmission occurring during high frequency and chemical stimulation of the SN robustly increases NO efflux in the dorsal striatum. Taken together with recent behavioral studies (see Introduction and below), these observations suggest that dopaminergic and nitergic systems are likely to interact in a complex manner to control purposeful and motivational behavior.

SN Stimulation Induces NO Efflux via Activation of Neuronal NOS

Systemic administration of either MB or 7-NI attenuated NO efflux evoked by SN stimulation indicating that the oxidation signal was largely dependent on NOS activation. Given that all three isoforms of the NOS enzyme can be found in the brain under normal or pathological conditions (Bredt *et al*, 1990; Dinerman *et al*, 1994; Madrigal *et al*, 2001), it is important to determine the source of NO evoked during SN stimulation. Previous studies using intact preparations have shown that 7-NI is a selective inhibitor of the neuronal isoform of NOS (Moore and Bland-Ward, 1996). The dose of 7-NI utilized (25 mg/kg, i.p.) in our experiments reduced NO efflux evoked by SN stimulation by approximately 50%. These observations are consistent with previous studies reporting that 7-NI (25 mg/kg, i.p.) produced half-maximal inhibition (EC₅₀) of striatal NOS activity as assessed *ex vivo* (30 min postinjection; Kalisch *et al*, 1996) and indicate that SN stimulation increases striatal NO efflux via an nNOS-dependent mechanism.

NO signaling generated from nNOS has been intricately linked to locomotor activity. Thus, nNOS inhibitors have been shown to block or decrease basal locomotor activity (Stewart *et al*, 1994) and the behavioral effects of various psychoactive drugs including phencyclidine, methylphenidate, nicotine, methamphetamine, cocaine, amphetamine, apomorphine, morphine, caffeine, and ethanol (Itzhak, 1997; Przegalinski and Filip, 1997; Itzhak and Martin, 2000, 2002; Li *et al*, 2002a,b; Zarrindast *et al*, 2003; Shin *et al*, 2003; Ulusu *et al*, 2005; Kayir and Uzbay, 2004; Klammer *et al*, 2004a,b). On the other hand, the administration of L-arginine and NO generators has been reported to

increase morphine- (Shin *et al*, 2003), amphetamine-, and cocaine-induced hyperlocomotion (Przegalinski and Filip, 1997). Additional studies have shown that cocaine- and methamphetamine-induced sensitization is abolished in nNOS(−/−) mice (Itzhak *et al*, 1998a,b). Furthermore, direct DA agonist-induced locomotor activity, including that of the D_{1/5} agonist SKF 38393, has been shown to be attenuated or potentiated by nNOS inhibition (7-NI) and NO donor (molsidomine) administration, respectively (Przegalinski and Filip, 1997). NOS inhibitors have also been shown to reduce movement stimulated by DA D₁ and D₂ agonists (Starr and Starr, 1995), while D₂ antagonist-induced catalepsy was potentiated (Cavas and Navarro, 2002).

SN Stimulation Increases NO Efflux via a D_{1/5} Receptor-Dependent Mechanism

To shed more light on the interaction between dopaminergic and nitrergic systems, we investigated the role of DA D_{1/5} receptor activation in mediating SN-induced striatal NO efflux. The D_{1/5} antagonist SCH 23390 was observed to attenuate NO efflux evoked by both electrical (train) and chemical SN stimulation. A role for D_{1/5} receptor activation in stimulating striatal nNOS activity and inducing NO release was also supported by the observation that intravenous administration of the selective D_{1/5} agonist SKF 81297 (in the absence of SN stimulation) induced an increase in NO release, which was blocked in the same animals by SCH 23390. This effect was observed in animals which also exhibited increases in NO efflux during train stimulation of the SN, indicating that NOS neurons are activated by endogenous DA and D_{1/5} agonist in these rats. These results extend previous histochemical studies showing that NOS activity, assayed via NADPH-diaphorase staining, is reduced following the administration of the D_{1/5} antagonist SCH 23390 (Morris *et al*, 1997). Consistent with our findings, D_{1/5} agonist administration has been shown to robustly stimulate the firing activity of electrophysiologically identified NOS interneurons in a manner sensitive to SCH 23390 administration (Centonze *et al*, 2002). Moreover, given that SKF 38393 depolarized the membrane of NOS cells in the presence of TTX, it is likely that DA exerts the majority of its facilitatory effects via a direct D_{1/5} receptor-dependent mechanism (Centonze *et al*, 2002).

Indirect evidence also exists indicating that striatal D₁-like receptor stimulation increases NO transmission. Thus, the facilitation of striatal acetylcholine release by SKF 38393 was blocked by local infusion of a nonspecific NOS inhibitor (Steinberg *et al*, 1998), indicating that D_{1/5} agonist-induced increase in NO transmission may stimulate the activity of cholinergic interneurons (Centonze *et al*, 2001). SKF 38393 has also been shown to increase striatal tissue levels of cGMP in a manner sensitive to SCH 23390 (Altar *et al*, 1990). Given that striatal cGMP levels are robustly increased by NO donors (Tsou *et al*, 1993; Globus *et al*, 1995; Wykes *et al*, 2002), it is likely that the D_{1/5} agonist-induced increase in cGMP observed by Altar and co-workers was at least partially mediated by an indirect D_{1/5} receptor-dependent activation of striatal NOS activity.

In contrast to our findings and the above-mentioned studies, Iravani *et al* (1998) have reported that local pressure ejection of DA into striatal slices did not increase NO efflux as measured by fast cyclic voltammetry. It is difficult to reconcile our observations with the above study given that the authors did not include the data in their report or indicate how many attempts were made to assess the impact of exogenous DA on NO efflux. A likely explanation for these discrepant findings is the difference in electrode size/sampling area between studies. The active surface of the NO microelectrodes utilized in our study was much larger (200 μm diameter, 4–5 mm length) than those utilized by Iravani *et al* (7 μm diameter, 20–30 μm length). Thus, we were able to assess the impact of endogenous DA and D_{1/5} agonist on NO efflux sampled across relatively large striatal subregions.

Role of Nitrergic Transmission in Striatal Function

Ultrastructural studies have demonstrated that NOS immunoreactive processes target the dendritic spine shafts of striatal MSNs (Morello *et al*, 1997; Sancesario *et al*, 2000; Calabresi *et al*, 2000b; Hidaka and Totterdell, 2001). Research characterizing the subcellular localization of GC second messenger pathways downstream of these nitrergic inputs also supports a role for NO in regulating striatal MSN activity (Ariano, 1983; Walaas *et al*, 1989; Fujishige *et al*, 1999). NO-dependent stimulation of GC results in increased DA- and cyclic-AMP-regulated phosphoprotein-32 (DARPP-32) activity in striatal slices (Nishi *et al*, 2005). Moreover, electrophysiological studies *in vitro* have demonstrated that NO efflux evoked by high-frequency stimulation of corticostriatal pathways modulates the long-term synaptic plasticity of MSNs via the activation of the GC signaling cascade and DARPP-32 (Calabresi *et al*, 1999a,b, 2000a,b). Our previous studies *in vivo* also indicate that tonic NO-GC signaling can enhance the membrane excitability of striatal neurons exhibiting electrophysiological and morphological characteristics of MSNs (West *et al*, 2002; West and Grace, 2004). Interestingly, a recent study demonstrated that phosphodiesterase 1B knockout mice exhibit hyperlocomotion, elevated DARPP-32 phosphorylation in response to DA D_{1/5} agonist, and spatial-learning deficits (Reed *et al*, 2002). Selective ablation of striatal NOS and cholinergic interneurons was also shown to alter behavioral and immediate early gene responses to DA agonists (Saka *et al*, 2002). Thus, NO and DA may act in concert to modulate the synaptic activity and membrane properties of MSNs containing GC, PKG, PKA, DARPP-32, and/or other DA signaling molecules.

Taken together, these observations indicate that a dysfunction in striatal nitrergic neurotransmission can disrupt information processing in MSNs and result in dysregulation of neurotransmission in basal ganglia circuits. In support of this, a recent study utilizing quantitative EEG methods has shown that inhibition of nNOS activity has a major impact on electrical activity patterns within corticostriatopallidal circuits (Ferraro *et al*, 2002). Additionally, we have observed that NO-dependent modulation of striatal neuron activity regulates the activity of DA neurons in the SN via striatonigral feedback pathways (West and Grace, 2000). Moreover, several studies reporting

that measures of nNOS activity are depressed in 6-OHDA-lesioned animals (de Vente *et al*, 2000; Sahach *et al*, 2000; Sancesario *et al*, 2004) suggest that nitrergic transmission may be compromised in patients with PD. This possibility is substantiated by studies demonstrating that striatal NOS-immunopositive cell numbers and mRNA are significantly depleted in post-mortem Parkinsonian brains (Bockelmann *et al*, 1994; Eve *et al*, 1998).

Conclusions

The current study is, to our knowledge, the first to demonstrate directly that striatal nNOS is stimulated *in vivo* by phasic activation of midbrain DA cells via a DA D_{1/5} receptor-dependent mechanism. These findings are consistent with previous reports that D_{1/5} receptor activation increases indirect measures of NOS activity (Altar *et al*, 1990; Morris *et al*, 1997) and firing activity of electrophysiologically identified NOS interneurons (Centonze *et al*, 2002). Thus, striatal NOS interneurons may be potentially activated by DA cell burst firing in specific behavioural contexts. This implicates DA-induced release of NO in the control of motivational behavior and thus suggests novel potential therapeutic targets for the treatment of neurological and psychiatric disorders.
