The guidelines for follow-up of breast cancer patients concentrate on the first 3–5 years, with either reduced frequency of visits or discharge after this. They also recommend mammography, but no evidence exists to inform frequency. We analyse treatable relapses in our unit from 1312 patients with early stage breast cancer treated by breast conserving surgery (BCS) and postoperative radiotherapy between 1991 and 1998 to assess appropriateness of the guidelines. A total of 110 treatable relapses were analysed. Treatable relapse developed at 1–1.5% per year throughout follow-up. Forty-eight relapses were in ipsilateral breast, 25 ipsilateral axilla, 35 contralateral breast, 2 both breasts simultaneously. Thirty-seven relapses (33.5%) were symptomatic, 56 (51%) mammographically detected, 15 (13.5%) clinically detected, 2 (2%) diagnosed incidentally. Mammography detected 5.37 relapses per 1000 mammograms. Patients with symptomatic or mammographically detected ipsilateral breast relapse had significantly longer survival from original diagnosis ($P=0.0002$) and from recurrence ($P=0.0014$) compared with clinically detected. Treatable relapse occurs at a constant rate for at least 10 years. Clinical examination detects a minority (13.5%). Relapse diagnosed clinically is associated with poorer outcome. Long-term follow-up based on regular mammography is warranted for all patients treated by BCS. *British Journal of Cancer* (2007) **96**, 1802–1807. doi:10.1038/sj.bjc.6603815 www.bjcancer.com

Historically, follow-up in breast cancer has focused on the early detection of relapse. The approach to detecting locoregional and metastatic relapse has changed as understanding of the natural history of the disease has improved. The diagnosis of incurable metastatic disease when patients are still asymptomatic does not significantly alter outcome (Del Turco *et al*, 1994; The GIVIO investigators, 1994). Moreover, regular visits are likely to increase distress and reduce quality of life, and may lead to unnecessary treatment (Del Turco *et al*, 1994; The GIVIO investigators, 1994). Tests to detect metastatic disease are no longer recommended (National Institute for Clinical Excellence, 2002).

Unlike metastatic relapse, it is generally accepted that, particularly in patients who have had breast-conserving surgery, locoregional relapse is potentially treatable and should be detected early (Clark *et al*, 1985; Recht *et al*, 1989; Fowble *et al*, 1990; Kurtz *et al*, 1990; Haffty *et al*, 1991; Dalberg *et al*, 1998). Regular periodic mammography and clinical examination are performed to detect asymptomatic ipsilateral and contralateral disease. However, in a recent meta-analysis routine clinic visits were at best inefficient in the detection of treatable locoregional relapse (de Bock *et al*, 2004). We have previously reported that only one-third of these are detected by clinicians at routine visits in asymptomatic patients, representing one relapse detected for every 175 routine clinic visits

(Jack *et al*, 1998). Despite locoregional relapse being relatively rare, and most such relapses being detected by other means, many clinicians still consider routine clinical examination necessary for detection of relapse. Increasingly, less frequent or shorter follow-up is being advised in an attempt to improve efficiency. While reduced follow-up has been shown to be acceptable to patients (Gulliford *et al*, 1997), little is known of its impact on loco-regional relapse detection and overall survival.

We have examined the pattern of treatable relapse in our unit, particularly with regard to its timing and method of detection, relating our findings to current guidelines to highlight their likely effect on our patients.

PATIENTS AND METHODS

Between 1991 and 1998, 1312 patients were treated for early stage breast cancer by breast conservation surgery, axillary node sampling or clearance and postoperative radiotherapy to the breast +/– ipsilateral lymphatics. Systemic therapy was given according to local and national guidelines. Follow-up was shared between the Edinburgh Breast Unit and the Department of Clinical Oncology, Western General Hospital, Edinburgh.

Although initial clinical follow-up consisted of 3–4 monthly visits for the first 2 years, 6 monthly for 3 years then annual visits until the tenth anniversary, from 2000, all patients were changed to annual follow-up visits only. Throughout, all patients were instructed in regular breast self-examination. Additional interval

visits for assessment were arranged by patients, their general practitioner or other health-care professionals as required. Patients were usually discharged to the national breast screening unit at 10 years. Annual bilateral mammography was undertaken throughout. Median follow-up was 10 years, range 1.5–15 years.

Characteristics of the included patients are presented in Table 1.

Locoregional relapse was defined as any relapse in the ipsilateral breast and axilla or the contralateral breast. Contralateral breast cancers are included here as the risk of subsequent contralateral breast cancer in patients who have had a previous breast cancer is 3–5 times greater than the population risk (Mellink *et al*, 1991). As such, detecting new contralateral cancers is an important component of breast cancer follow-up programmes. Supraclavicular relapse was included with metastatic disease. Detection of metastatic disease within 3 months of locoregional relapse was considered to constitute simultaneous local and distant relapse and these patients were excluded from the analysis.

A list of all patients known to have suffered an isolated locoregional relapse or new contralateral cancer was generated from our database in January 2006. A retrospective study of these case records was then undertaken. Time from diagnosis to relapse, method of detection of relapse (routine mammography, routine clinical examination in an asymptomatic patient or investigation of a patient who attended complaining of relevant symptoms) and type of clinic (routine or interval) was recorded. Time from relapse to development of metastatic disease or death was then calculated and survival was compared for each mode of detection. For all relapses detected clinically in the first instance, we established whether the relapse was also visible on mammography.

RESULTS

Between 1991 and 1998, 1312 patients were treated for primary operable breast cancer by breast conservation surgery. Figure 1 displays overall survival, Figure 2 cause specific survival. The

overall 5-year survival was 89.2%; 10-year survival was 77.2%. Not included in the analysis were 31 patients with synchronous locoregional and metastatic disease and 11 with metastatic disease before locoregional relapse; these are included as metastatic relapse in Figure 3 (see below). A total of 116 patients suffered an isolated locoregional relapse. After exclusion of four lacking available records, and two lost to follow-up through moving away from the area, 110 patients were left for analysis. Details of all patients with treatable relapse are shown in Table 2.

48 patients developed ipsilateral breast relapse, 11 with concomitant axillary disease. Twenty-five patients had isolated ipsilateral axillary relapse and 35 developed new contralateral cancers. One patient developed ipsilateral breast and axillary relapse and a new contralateral cancer simultaneously and one developed ipsilateral breast relapse and a new contralateral cancer simultaneously.

The recurrence rate in this cohort is presented as Figure 3. The incidence of metastatic relapse peaks at just over 3% per annum at 2–3 years and remains above 2% per year for up to 5 years before falling off. In contrast, the incidence of locoregional relapse remains constant at 1–1.5% over the whole follow-up period.

Site of relapse and method of detection are summarised for the 110 patients in Table 3, together with the numbers who died (in brackets).

Interval appointments

Twenty-three of the 110 patients (21%) had relapse detected at an interval clinic visit of whom 22 complained of relevant symptoms, and the other had an abnormality noticed by careers. Of these 23 patients, 10 had ipsilateral breast relapse, 6 axillary relapse and 2 had synchronous breast and axillary relapse, with symptoms from both sites. Five patients discovered their new contralateral cancer.

Two patients (2%) were referred back to clinic having been discharged from further follow-up at 10 years post-treatment. One

complained of symptoms related to axillary relapse (included in Table 3 as having been diagnosed at an interval clinic with symptoms) and one had abnormal routine breast screening mammograms, which indicated breast and axillary relapse (included in Table 3 as routine mammographically detected relapse).

Routine appointments

The remaining 85 relapses (77%) were detected at routine clinics or by routine mammography. The pattern of relapse and method of detection for this group is also presented in Table 3.

Of the four ipsilateral breast recurrences diagnosed clinically, the most recent annual surveillance mammogram was negative in two. Mammography was repeated and was negative in the third. In the fourth, mammography did reveal some distortion, but this was reported as benign post-surgical changes in their first routine follow-up mammogram 1 year after surgery. Neither of the two contralateral cancers detected clinically were visible on mammography. Of the nine axillary relapses diagnosed clinically, one also visible on mammography was included as a clinical diagnosis as it was diagnosed at a routine appointment at which mammography was not scheduled.

In total, 37 relapses (33.5%) were symptomatic, 56 (51%) mammographically detected, 15 (13.5%) clinically detected and 2 (2%) were diagnosed incidentally.

A total of 10 415 mammograms were undertaken during follow-up, with 56 treatable relapses diagnosed that is 5.37 treatable relapses per 1000 mammograms.

Survival

Details of the 37 deaths among the 110 patients during the follow-up period are shown in Table 3.

Ipsilateral breast Forty-eight patients suffered ipsilateral breast recurrence, of whom 11 had additional axillary recurrence. Overall

5-year survival was 87.5% from original operation, and 64% from diagnosis of recurrence. Survival by method of detection is shown below (Figure 4).

Overall survival was significantly reduced among those with recurrence diagnosed clinically compared with either other method (log rank 2 df $P=0.0002$). This remains highly significant even if cases with axillary disease are excluded ($P=0.0004$), and reflects a significantly longer survival from recurrence (Figure 5) (log rank 2 df $P=0.0014$) rather than a difference in time to recurrence detection.

The pathological characteristics of the recurrent disease are presented as Table 4. Mean age at recurrence is also shown. Nodal status was available for all 48 patients. Size of the recurrent lesion was unavailable for 10 women, with grade of the recurrence unavailable for 13. Receptor status was seldom available. Trends for those with clinically detected relapse to be older than others, and for mammographically detected lesions to be smallest at detection, with symptomatic largest, were not significant. Overall, there was no significant difference in any of the clinicopathological features in relation to how relapse was detected, and Nottingham Prognostic Index of the relapse was similar for all three groups.

Contralateral breast There was no association between method of detection of relapse and survival in patients who developed a new contralateral breast cancer. However, 25 out of 35 of these (71%) were diagnosed by mammography with 8 self-diagnosed and 2 picked up on clinical examination. Both of the patients with new cancers detected clinically were well at last follow-up. Overall 5-year survival from time of relapse for all patients with contralateral breast relapse was 81%.

Grade 1: 2	Grade 1: 3	Grade 1: 1
Missing: 4	Missing: 7	Missing: 1
Proportion of relapses with positive lymph nodes 2 of 17 (8.5%)	1 of 4 (25%)	7 of 25 (28%)
Mean NPI ^a of recurrence 4.36 (s.d. 1.33)	4.02 (s.d. 1.26)	3.87 (s.d. 1.16)

^aNPI = Nottingham Prognostic Index. **Figure 5** Survival from time of relapse in patients with ipsilateral breast relapse.

Ipsilateral axilla There was similarly no association between method of detection of recurrence and survival in patients who had isolated ipsilateral axillary relapse, although the numbers overall were small. Overall 5-year survival from time of relapse for patients with axillary relapse was 61%.

DISCUSSION

The most recent guidelines for the follow-up of breast cancer patients from the American Society of Clinical Oncology (ASCO) recommend 3–6 monthly follow-up for 3 years, 6–12 monthly for 2 years then annual follow-up (Khatcheressian *et al*, 2006). No advice is given regarding discharge, although 1999 guidelines recommended this at 10 years (American Society of Clinical Oncology, 1999). In Canada, the Steering Committee guidelines state that there is no compelling evidence to support any particular frequency of clinic visits, but concludes that visits should be more frequent initially due to a higher risk of recurrence in the first few years, reducing to annual after 3–5 years and being continued indefinitely (The Steering Committee on Clinical Practice Guide-

lines for the Care and Treatment of Breast Cancer, 1998). Annual mammography is recommended by both groups, although ASCO acknowledge the lack of good evidence (Khatcheressian *et al*, 2006).

In contrast, the recent guidelines for England and Wales (NICE) recommend follow-up of only 2–3 years in total, but leave frequency of visits open (National Institute for Clinical Excellence, 2002). The British Association of Surgical Oncology (BASO) recommends slightly longer follow-up, with discharge at 5 years, again leaving frequency of visits open (The Association of Breast Surgery @ BASO and Royal College of Surgeons of England, 2005). Neither group recommends how often mammography should be performed, with NICE stating that evidence-based protocols should be agreed locally, and BASO referring to the Royal College of Radiologists advice that mammography should be every 1–2 years (The Royal College of Radiologists, 1995).

Although these guidelines appear to vary markedly, all assume that relapse is commonest in the first few years after treatment. A greater hazard rate for relapse during the first 3 years was just evident in the ATAC trial (The ATAC Trialists' Group, 2005), but reflects a higher rate of distant relapse in this period. Others have reported that the rate of locoregional relapse is initially high, and then falls off, so that most treatable relapses occur in the first 3–5 years (Elder *et al*, 2006). However, these studies do not include new contralateral cancers. Other studies have a very brief median follow-up, without analysis of recurrence over the long term (Donnelly *et al*, 2001). The present study confirms that rate of distant relapse peaks in the first 5 years, but this is not mirrored by the pattern of locoregional relapse, which remains constant at 1–1.5% for at least 10 years. Others have also reported that while the incidence of true local recurrence declines with time, that of new breast cancers in other areas of the previously treated breast and new contralateral breast cancers increases with time, so that the overall rate of treatable relapse remains constant for over 15 years (Freedman *et al*, 2005).

The second assumption in various guidelines is that clinical examinations are of particular value, with more frequent visits recommended during the perceived high-risk period of the first few years. Previous studies have consistently shown that multiple clinical visits do little to increase yield and only serve to reduce the 'cost effectiveness' of follow-up (de Bock *et al*, 2004). Our data confirm this. In 10 years of follow-up in 1312 women, only 15 relapses were detected clinically. This is a very low yield. Mammography in contrast makes a much larger and more significant contribution to relapse detection, not only in the area of contralateral new breast cancer detection but also in detecting ipsilateral breast recurrence. In fact, a detection rate of 5.37 cancers per 1000 mammograms is higher than that reported as recently as 2003 by the breast screening service in the UK that carries out 3-yearly mammography (NHS Cancer Screening Programmes, 2003), and is equivalent to that in this body's latest (2007) report.

Why patients with clinically detected relapse do less well is unclear from this study, and although slightly older on average, the difference was not significant. Nottingham Prognostic Index for the relapse was similar for all three methods of detection.

Our data reveal that the basic assumptions behind the guidelines for follow-up are incorrect. If a central aim is the detection of treatable relapse, as stated in the guidelines, there is no justification for focussing on the first 2–3 years after treatment; treatable relapse occurs at a constant rate over at least 10 years. Our data suggest that clinical examinations do not improve outcome. Women are well schooled in self-surveillance of their breasts. Axillary relapse, on the contrary, is more frequently detected by clinicians, 36% being so detected. However, isolated axillary relapse was relatively rare, with just 25 in 1312 patients over 10 years, and only nine clinically detected relapses. We intend to highlight the need for regular axillary self-examination, not

previously stressed, and hope this will further improve the yield of self-examination, particularly in this era of sentinel lymph node biopsy.

Detection of treatable relapse is only one of the aims of follow-up. Additional aims concern psychological problems and adverse effects of therapy, particularly lymphoedema (National Institute for Clinical Excellence, 2002). It is uncertain whether routine clinic visits achieve these aims. While women do find clinics reassuring when told they do not have recurrence (Morris *et al*, 1992; Kiebert *et al*, 1993), visits are also attended by great anxiety (Paradiso *et al*, 1995). There is little doubt that clinicians are not good at detecting psychological problems in the clinical setting (Hardman *et al*, 1989; Passik *et al*, 1998) and patients are reluctant to report such psychological problems themselves (Valente *et al*, 1994; Pennery and Mallet, 2000). Certainly, one study has shown no reduction in quality of life among women randomised to receive no routine clinic visits compared with regular visits (Gulliford *et al*, 1997).

Whether routine clinics are necessary for the detection and treatment of adverse effects of therapy is also uncertain. Detection of lymphoedema is given central importance in the NICE guidelines, although its symptoms do not correlate with objective

measurements of arm swelling (Schunemann and Willich, 1998). Moreover, there is little in the way of an effective therapy. Side effects of treatment might be detected better by education and focussing follow-up on the symptomatic individual.

Aromatase inhibitors have introduced a new consideration in follow-up. The NICE guidelines only mention adjuvant hormonal therapy to say that the general practitioner should be responsible for stopping it at 5 years (National Institute for Clinical Excellence, 2002). With recent indications for switch and extended aromatase treatments, which are instituted in specialist care, discharge to general practice after 3 years would not be appropriate. Moreover, hormonal therapy can significantly impact patients' overall well being, particularly in the first 3 months of therapy (Fallowfield *et al*, 2004). Patients should have access to specialist advice to help ameliorate any symptoms. Long-term rapid and flexible access to specialist care would be ideal in the face of new developments in breast cancer treatment, and emphasis should be placed on psychological and physical well-being. It is also likely that new hormonal therapies will alter the pattern of relapse so that even fewer relapses occur in the first 3 years after treatment (The ATAC Trialists' Group, 2005).
