Variants of the transforming growth factor-beta receptor type I (TGFBR1) gene, TGFBR1*6A and Int7G24A, have been suggested to act as low-penetrance tumour susceptibility alleles with TGFBR1*6A being causally responsible for some cases of familial colorectal cancer (CRC). We performed a case-control study of 262 unrelated familial CRC cases; 83 hereditary non-polyposis colorectal cancer (HNPPC) and 179 non-HNPPC. Patients were genotyped for TGFBR1*6A and Int7G24A and compared with 856 controls. Further, we screened the coding region of TGFBR1 in affected members of a large family with CRC linked to 9q22.32-31.1. TGFBR1*6A allelic frequency was not significantly different in all of the familial cases compared with controls (0.107 and 0.106, respectively; $P = 0.915$). In a subgroup analysis allele frequencies were, however, different between HNPPC and non-HNPPC familial cases (0.157 and 0.084, respectively; $P = 0.013$). TGFBR1*6A genotype did not influence age of onset. Int7G24A allele frequencies were similar in cases and controls. No germ-line mutation was identified in the family with CRC linked to this chromosomal region. Our study provides no substantial support for the hypothesis that the polymorphic variants TGFBR1*6A or Int7G24A contribute to familial CRC risk. We cannot, however, exclude the possibility that TGFBR1 variants have a modifying effect on inherited risk *per se*. *British Journal of Cancer* (2009) **100**, 1674–1679. doi:10.1038/sj.bjc.6605054 www.bjcancer.com

Colorectal cancer (CRC) is the third most common cause of cancer-related mortality in the Western countries, and in the United States it represents the second most common cause of cancer mortality (Parkin, 2001). Although 35% of all CRC seems to involve an inherited susceptibility (Lichtenstein *et al*, 2000). Mendelian predisposition syndromes associated with mutations in known genes (such as APC, DNA mismatch repair genes (MMR), MYH, SMAD4, BMPRIA/ALK3 and STK11/LKB1) collectively only account for 5% of disease burden (Lichtenstein *et al*, 2000; Lynch and de la Chapelle, 2003). The nature of the remaining heritability is undefined, but a model in which part of the inherited risk is conferred by common, low-penetrance alleles seems highly probable and has been the rationale for seeking to identify disease alleles through association analyses.

Transforming growth factor- β (TGF- β) is a potent inhibitor of cell growth influencing the behaviour of a number of cancers (Derynck *et al*, 2001). The TGF- β mediates its action through a heteromeric cell-surface complex of two types of transmembrane serine/threonine kinases, TGF- β receptor type 1 (TGFBR1) and type 2 (TGFBR2) (Lin *et al*, 1992; Ebner *et al*, 1993). The TGFBR2 gene is mutated in several cancer types with ~90% of colon

cancers characterized by MMR deficiency displaying frameshift mutations in a polyadenine tract of TGFBR2, which encodes the signal peptide of the expressed protein (Parsons *et al*, 1995).

A relatively common variant of the TGFBR1 gene, TGFBR1*6A, is caused by deletion of three GCG triplets coding for alanine within a nine alanine (*9A) repeat sequence of exon 1, reportedly associated with less TGF- β growth inhibitory signalling capacity than the native expressed protein (Chen *et al*, 1999; Pasche *et al*, 1999). In some epidemiological studies, the TGFBR1*6A allele has been reported to be associated with an increased risk of a number of different malignancies, including CRC (Pasche *et al*, 1999; Chen *et al*, 2001; Baxter *et al*, 2002; Kaklamani and Pasche, 2005). In addition, the TGFBR1*6A variant has been proposed to be directly causally responsible for a proportion of hereditary non-polyposis colorectal cancer (HNPPC), especially those without MMR deficiency (Bian *et al*, 2005). Intriguingly, TGFBR1 maps to chromosome 9q22.32-31.1, a from several independent studies suggested CRC susceptibility locus (Wiesner *et al*, 2003; Kemp *et al*, 2006; Skoglund *et al*, 2006).

Another polymorphic variant of TGFBR1, Int7G24A, has also been implicated in cancer susceptibility, associations with kidney, bladder, breast and non-small cell lung cancer being reported (Chen *et al*, 1999, 2004; Zhang *et al*, 2003).

To further evaluate the relationship between the TGFBR1 variants and CRC risk we determined whether these variants contribute to familial CRC. Using a case-control design, we compared TGFBR1*6A and Int7G24A allele frequencies in HNPPC

and non-HNPCC familial CRC cases with population-based controls. We also examined whether germ-line *TGFBRI* mutations are responsible for the CRC susceptibility locus on chromosome 9 by screening the entire coding region of *TGFBRI* in affected members of a large family with adenoma and CRC linked to chromosome 9q22.32-31.1 (Skoglund et al, 2006).

MATERIALS AND METHODS

Study population

Two hundred and sixty-two families, ascertained through the Family Cancer Clinic at Karolinska University Hospital, Stockholm, Sweden during 1990–2006, were included in the study. A total of 83 families, all with a germ-line mutation in one of the MMR genes, were considered as HNPCC and 179 families were diagnosed and counselled as non-HNPCC according to our earlier published protocol (Lagerstedt Robinson et al, 2007). From each family one case was selected for case–control studies. The selection was made using the following priority order; (1) proband (when affected), (2) youngest CRC case or (3) youngest case with adenoma. Statistical analysis was carried out on CRC plus adenoma cases and CRC cases alone. Epidemiological studies have shown that a personal history of colon adenomas places one at increased risk of developing CRC (Neugut et al, 1993; Jacobson and Neugut, 1996; Liljegren et al, 2003). Furthermore, adenomas are over-represented in CRC families and first-degree relatives of patients with large adenomas are at increased risk of developing CRCs or large adenomas (Lindgren et al, 2002; Cottet et al, 2007). Removal of adenomatous polyps is associated with reduced CRC incidence (Muller and Sonnenberg, 1995; Winawer et al, 2000). Eight hundred and fifty-six blood donors from the Karolinska University Hospital, Stockholm, Sweden served as source of control DNA.

For mutation screening of *TGFBRI*, we analysed genomic DNA from a family with CRC and adenoma linked to chromosome 9q22.32-31.1. A full description of this family has been published earlier (Skoglund et al, 2006).

The study was undertaken in accordance with the Swedish legislation of ethical permission (2003:460) and the Stockholm regional ethical committee (Dnr: 2000/291, 2005/566) in accordance with the Declaration of Helsinki.

Genotyping

The *TGFBRI**6A variant was determined by PCR amplification using fluorescently labelled primers Fwd- 5'-GAGGCGAG GTTTGCTGGGGTGAGG-3' and Rev- 5'-CATGTTTGAGAAAGAGC AGGAGCG-3'. Amplification was performed using the Platinum-Taq DNA polymerase and supplied protocol for GC-rich fragments (Invitrogen, Carlsbad, CA, USA). Amplified fragments were separated by electrophoresis on an ABI 377 semi-automated DNA Sequencer (Applied Biosystems, Bedford, MA, USA) and genotypes assigned using GENESCAN and GENOTYPER software (Applied Biosystems). A product size of 256 bp corresponded to the most common allele, *9A, whereas a product size of 247 bp corresponded to the *6A allele. Besides the *9A and *6A alleles, we observed three rare alleles (Figure 1). The *5A/*9A genotype was detected in one non-HNPCC case and one control case. Another two individuals with a *7A/*9A genotype and one individual with a *9A/*10A genotype was detected, all in the control group. All these rare alleles have been reported earlier (Pasche et al, 1999; Spillman et al, 2005). All *6A homozygotes and *6A/*9A heterozygotes and all samples with rare alleles were retyped after a second independent PCR amplification to confirm the allele calling.

Genotyping of the Int7G24A variant was performed by PCR amplification of intron 7 using primers Fwd- 5'-GGAGGTTTCATC

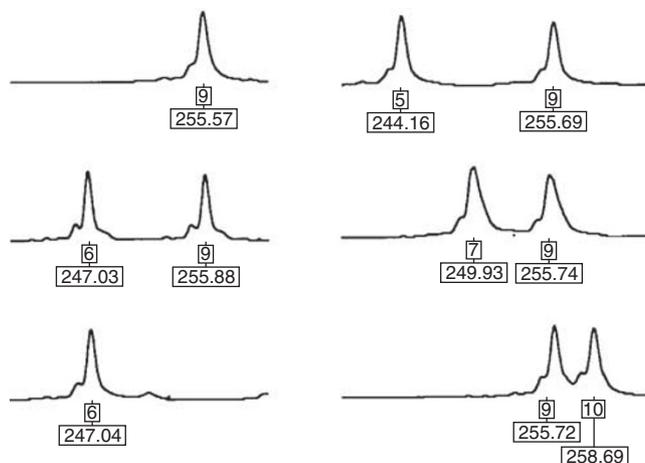

Figure 1 Representative electropherograms of the *9A/*9A, *6A/*9A, *6A/*6A, *5A/*9A, *7A/*9A and *9A/*10A genotypes. Allele and size in base pairs are indicated below each peak.

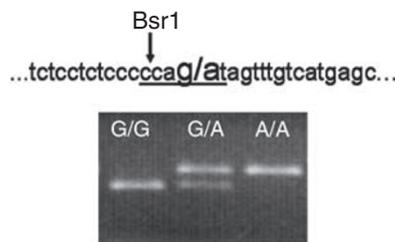

Figure 2 Genomic sequence surrounding the Int7G24A variant and a representative photograph of the PCR-RFLP analysis. The variant site is marked in bold and the BsrI recognition site is underlined. BsrI recognises and cuts the wild-type sequence (smaller band) whereas the variant abolishes the BsrI restriction site (larger band).

CAAATATGGC-3' and Rev- 5'-CTCTGGCACTCGGTGACAT-3' followed by BsrI digestion and visualisation on a 2.5% agarose gel (Figure 2). For 85 samples, restriction enzyme digestion was replicated after a second independent PCR amplification to confirm the allele calling. Further details on genotyping can be obtained from the authors.

Mutation screening of TGFBRI

Mutational analysis of *TGFBRI* was conducted on germ-line DNA from affected individuals in family 24 carrying the linked haplotype using a combination of denaturing high performance liquid chromatography (dHPLC) (exons 2–9 + 1091 bp upstream of exon 1) and direct sequencing (exon 1 + 3'UTR). Details on family 24 have been published earlier (Skoglund et al, 2006). Owing to stringent surveillance only one individual alive (Co-166) had developed CRC. Individual Co-166 was mutation screened for all fragments. The selection of additional individuals for mutation screening was carried out based on carrier status of the linked haplotype along with grade of affected status.

Screening for genomic deletions and rearrangements was performed using reverse transcriptase–PCR. RNA from two affected individuals (Co-186 and Co-213) plus two controls was extracted with the Qiagen RNeasy kit (Operon Biotechnologies, Huntsville, AL, USA) and reverse-transcribed with a first-strand synthesis kit (Amersham Biosciences, Piscataway, NJ, USA). Primer sequences and details of all the assays are available on request.

Statistical methods

Risks associated with TGFBRI genotypes were estimated by odds ratios (ORs) using unconditional logistic regression, and associated 95% confidence intervals (CIs) were computed. To test for population stratification the distribution of genotypes were tested for a departure from Hardy–Weinberg equilibrium. Differences in the distribution of continuous variables were compared using Mann–Whitney U-test or the statistics of Cuzick (1985) and Altman (1991) and between proportions by Fisher’s exact test.

Confidence limits for sequence changes among cases were computed under the assumption that frequencies followed a Poisson distribution. All statistical analyses were performed using STATA Version 7.0 (Stata Corporation, College Station, TX, USA). A P-value of 0.05 was considered statistically significant in all analyses.

RESULTS

The characteristics of the study participants are detailed in Table 1. Cases from HNPCC families were diagnosed with CRC younger than those from non-HNPCC families (45 years vs 57 years, respectively; P < 0.01) consistent with ascertainment selection.

The observed frequencies of TGFBRI*6A genotypes in cases and controls were in accordance with Hardy–Weinberg laws of equilibrium (P = 0.35 and 1.00 in familial non-HNPCC and HNPCC cases; P = 0.86 in controls), providing no evidence of population stratification within the dataset. The frequency of TGFBRI*6A was not significantly different between controls (0.106, 95% CI: 0.102–0.135) and all familial cases (0.107, 95% CI: 0.082–0.137; Table 2A). Confining the affection status to a diagnosis of CRC only and excluding adenomas did not change the results much (0.117, 95% CI: 0.087–0.151; Table 2B).

Eighty-three of the cases had HNPCC and 179 had non-HNPCC hereditary CRC. Among those with non-HNPCC; 26 (14.5%) and two (1.1%) were hetero- and homozygous for the TGFBRI*6A allele, respectively (TGFBRI*6A allele frequency 0.084). Of the 83 cases with HNPCC; 22 (26.5%) and two (2.4%) were TGFBRI*6A heterozygotes and homozygotes, respectively (TGFBRI*6A allele frequency 0.157). Of the 24 TGFBRI*6A carriers; 10 had a MLH1 mutation, 11 had a MSH2 mutation and three had a MSH6 mutation. Although the frequency of the TGFBRI*6A allele was similar in non-HNPCC familial cases and controls (0.084 and 0.106, respectively; P = 0.23), the frequency in HNPCC cases was markedly elevated (0.157; P = 0.045) compared with the controls. Hence, there was an apparent difference in TGFBRI*6A allele frequency between HNPCC and non-HNPCC familial cases (0.157 and 0.084, respectively; P = 0.013). Table 2A details the ORs of CRC and adenoma and corresponding 95% CIs associated with TGFBRI*6A hetero- and homozygosity in the two familial CRC groups. When performing test for association restricting affection

status in cases to CRC (non-HNPCC, n = 132; HNPCC, n = 82), corresponding ORs were similar (Table 2B).

To further explore the possibility that carrier status might affect CRC risk we compared the age of onset of CRC in *TGFBRI*6A* carriers and non-carriers. There was no association between age at diagnosis of CRC and *TGFBRI*6A* genotype (data not shown). Comparison of the cumulative distribution curves also showed no significant difference in carriers compared with non-carriers. Among familial non-HNPCC cases the average age at cancer diagnosis in *TGFBRI*6A* carriers and non-carriers was 58.4 years (s.d., 13.0) and 56.8 years (s.d., 10.6), respectively. Corresponding ages at diagnosis in carriers and non-carriers in HNPCC cases was 43.3 years (s.d., 11.0) and 45.7 years (s.d., 10.6), respectively.

In the study by Bian *et al* (2005), the highest *TGFBRI*6A* frequency was found among MMR mutation-negative cases with MSI-negative tumours. Data on tumour DNA samples evaluated for MSI status were available from 249 of the cases. Among all familial cases, *TGFBRI*6A* carrier frequency was not significantly different in MSI-positive cases compared with MSI negative ($P=0.17$). Among HNPCC cases with MSI tumours (MMR/MSI positive) over-representation of *TGFBRI*6A* carriers was evident, albeit non-significantly compared with the controls (data not shown). Subdividing the whole sample set by Amsterdam criteria and MMR status showed the highest *TGFBRI*6A* allelic frequency in Amsterdam criteria-positive families with a detected MMR gene mutation (0.198). On the contrary, the allelic frequency was zero in Amsterdam criteria-negative families with no detected MMR mutation.

The Int7G24A variant was successfully genotyped in 262 familial CRC cases, 179 non-HNPCC and 83 HNPCC, and 853 controls. The observed frequencies of Int7G24A genotypes in cases and controls were in accordance with Hardy–Weinberg laws of equilibrium ($P=1.00$ and 0.09 in familial non-HNPCC and HNPCC cases; $P=0.82$ in controls). There were no differences in allele or genotype frequencies between cases and controls or between the different types of familial CRC (Tables 3A and 3B).

In an earlier study, we have shown linkage of CRC and colorectal adenomas to chromosome 9q22.32–31.1 in a large Swedish family (family 24) (Skoglund *et al*, 2006). To exclude the possibility that sequence variation in *TGFBRI* is responsible for the linkage in the family, we screened for germ-line mutations in affected family

members. The *TGFBRI*6A* and Int7G24A variants were not on the linked haplotype. Two individuals (Co-213 and Co-219) were heterozygous *TGFBRI*6A* carriers. The remaining seven individuals with the linked haplotype were *9A homozygous. For the Int7G24A variant; the two individuals screened for this fragment (Co-166 and Co-648) were not carriers of this variant. No sequence change was detected on the linked haplotype.

DISCUSSION

Some studies have reported an over-representation of *TGFBRI*6A* in individuals with a number of different cancers fuelling speculation by Pasche *et al* (2004) that the *TGFBRI*6A* allele represents a low-penetrance allele with pleiotropic effects. The same research group reported a case-control study comparing *TGFBRI*6A* allelic frequency among HNPCC patients subdivided by first MMR gene mutations status and second tumour MSI status, observing a markedly elevated frequency of *TGFBRI*6A* carriers among MMR gene mutation-negative cases with the highest frequency among cases with MSI-negative tumours (Bian *et al*, 2005). On this basis they postulated that the *TGFBRI*6A* allele may be causally responsible for a proportion of non-HNPCC occurrence.

In contrast to Bian *et al* (2005) in our study *TGFBRI*6A* allelic frequency was not significantly different in all of the familial cases compared with controls. Moreover, in a subgroup analysis (which inevitably invokes the issue of multiple testing and apparent paradoxes) allele frequencies were only significantly different in HNPCC cases with a known MMR genetic defect, indicating a possible role if any as a modifying factor in HNPCC families. Further subdivision by MMR- and MSI status confirms this observation however, groups are small and differences were not significant. Further studies are needed to confirm this observation.

In our study, 48 cases affected with adenomas were included in the analysis. However, as shown in Table 2b excluding these did not change the results indicating that the *TGFBRI*6A* variant confers the same increased risk for adenoma as for CRC in these families.

The intronic variant, Int7G24A, has been variously associated with an increased risk of kidney-, bladder- and breast cancer

(Chen *et al*, 2004, 2006). Although our analyses were based on a smaller control dataset than that used for evaluation of TGFBR1*6A, we found no real evidence that Int7G24A influences CRC risk.

The pivotal role TGFBR1 plays in tumour development makes the hypothesis that germ-line variation in the gene may influence CRC susceptibility an attractive concept. A recent study has reported that germ-line allele-specific expression (ASE) of TGFBR1 is a quantitative trait detectable in 10–20% of CRC patients and 1–3% of the population (Valle *et al*, 2008). Moreover it was proposed ASE is dominantly inherited trait, if confirmed these findings are compatible for this association being responsible for >50% of the excess familial risk of CRC. Paradoxically, although two major TGFBR1 haplotypes were predominant among ASE cases (one of the two major haplotypes included TGFBR1*6A and overall 50% of ASE cases carried the TGFBR1*6A variant) no causal variant was identified.

In contrast to the findings of Valle *et al* (2008) in a large case-control study and meta-analysis of eight earlier published studies of the relationship between TGFBR1*6A and CRC, we found little evidence for the tenet that germ-line variation in the gene defined by this variant significantly influences CRC risk (Skoglund *et al*, 2007).

For this study, we had 262 families available for analysis. On the basis of published estimations of sample size needed for achieving adequate power to detect association our data set has limited power. However, analysing familial cases provide a means of generating a genetically enriched dataset with increased power to show associations compared with using unselected cases (Houlston and Peto, 2003). Without appropriate adjustment, however, derived genotypic risks computed are inflated, hence the upper confidence limits of the risk of CRC associated with the variants in our study will be overoptimistic.

As source of controls, we have employed blood donors. No data, because of policy of anonymity, was available for age, ethnicity, medical- or family history for these individuals. However, it is unlikely that this will have significantly influenced study findings as any age or gender difference from controls will be minimal. Furthermore, although the ethnicity data on blood donors was not

available these individuals were drawn from the same demographic region as the cases analysed making the probability of confounding from population stratification unlikely. Blood donors constitute a healthy cohort with a risk for later onset diseases, such as CRC close to that of the general population. Still, even if the controls are representative for the general population, cases included are not consecutive but constitute a cohort genetically enriched for risk alleles. Therefore, we used OR rather than the relative risk to calculate the risk associated with the variants.

Mutational analysis of TGFBR1 in the earlier published family 24 with CRC and adenoma linked to chromosome 9q22.32-31.1 (Skoglund *et al*, 2006) showed no sequence changes on the linked haplotype. Furthermore, the linked haplotype carried the normal sequence for the two studied variants, TGFBR1*6A and Int7G24A. Therefore, we can exclude these variants as disease causing in this family. This is in accordance with two recent studies where the TGFBR1*6A variant was investigated in a sample linked to this locus and excluded as the disease-causing variant (Kemp *et al*, 2006; Daley *et al*, 2007). The fact that the linked haplotype carried the normal sequence for the two studied variants TGFBR1*6A and Int7G24A means it is therefore different from at least one of the TGFBR1 ASE haplotypes reported by Valle *et al* (2008) which carried the TGFBR1*6A variant.

We cannot exclude the possibility that variants of TGFBR1 are associated with a small CRC risk modifying the impact of other gene effects. However, on the basis of our findings it seems unlikely that variation in TGFBR1 defined by the TGFBR1*6A and the Int7G24A makes a significant contribution to familial CRC risk.

ACKNOWLEDGEMENTS

This study was supported by the Cancer and Allergy Foundation, the Gustav the fifth Jubileé Foundation, the Nilson-Ehle Foundation, the Anders Otto Swärd Foundation, the FoU Foundation, the Swedish Research Council and the Swedish Cancer Society.
