Abstract

Prostate cancer (PCa) is the most frequently diagnosed malignancy and the second leading cause of cancer-related deaths in American males with similar trends in many western countries. The existing treatment approaches and surgical intervention have not been able to effectively cope with this dreaded disease. For these reasons, it is necessary to intensify our efforts for a better understanding of the disease process and for the development of novel approaches for its prevention and treatment. Based on considerable evidence from *in vivo* and *in vitro* data and epidemiological studies, in recent years the beverage tea has gained considerable attention for reducing the risk of several cancers. Much of the cancer preventive effects of tea, especially green tea appear to be mediated by the polyphenols present therein. Geographical evidence suggests that the incidence and occurrence of PCa is lower in populations that consume tea regularly. This evidence suggests that tea polyphenols could be extrapolated to optimize their chemopreventive properties against PCa. PCa represents an excellent candidate disease for chemoprevention because it is typically diagnosed in men over 50 years of age and therefore, even a modest delay in neoplastic development achieved through pharmacological or nutritional intervention could result in a substantial reduction in the incidence of clinically detectable disease. In this review we address the issue of possible use of tea, especially green tea, for the prevention as well as treatment of PCa.

Introduction

Prostate cancer (PCa), one of the most invasive and most frequently diagnosed male malignancies in the United States, is the second leading cause of cancer-related deaths in American males with similar trends in other western countries^[1]. In the year 2002, 679 023 new cases were reported worldwide and the disease killed 221 002 (three-quarters of all cases are in men aged 65 or more) making this the fifth most common cancer in the world and the second most common in men (11.7% of new cancer cases overall; 19% in developed countries and 5.3% in developing countries)^[2]. According to a projection by the American Cancer Society, approximately 218 890 men will be diagnosed with PCa in the USA in the year 2007, and 27 050 PCa-related deaths are predicted^[1].

The incidence of PCa increases rapidly with advancing age, and multiple genetic and epigenetic factors have been implicated in the development of PCa. Despite the substantial morbidity and mortality, the etiology of PCa is poorly understood. The limitations in the clinical management of PCa are derived not only from the fact that no single gene or molecule has served as a reliable marker of PCa but also from the reality that, as yet, an effective therapeutic regimen for its treatment is lacking. It is increasingly appreciated that environment and lifestyle, particularly dietary habits, also contribute substantially to the disease outcome^[3]. It is of interest that in western countries PCa is more prevalent than their eastern counterparts, possibly due to the varied divergence in their dietary habits (Figure 1).

Evidence from geographic, epidemiological and *in-vitro*

Figure 1. Incidence and mortality rates for prostate cancer in Western and Asian countries (adapted from Parkin *et al*^[2])

and *in-vivo* experiments suggest that environmental carcinogenic factors and nutrition play important causative roles in the initiation, promotion and progression of PCa^[4-7]. Although clinical PCa incidence and mortality vary greatly among populations^[3,8], the frequency of latent PCa is evenly distributed. The rising incidence of PCa in several countries that previously were considered to have low incidence rates appear to be coincident with the adoption of western lifestyle in those populations, implicating factors such as low levels of physical activity, high relative body weight and high dietary fat intake in the pathophysiology of PCa^[9]. While environmental carcinogenic factors are difficult to control, dietary habits can easily be modified based only on individual decisions.

One case-control study has shown a positive association of PCa risk with total energy intake, as well as total fat intake^[10]. These observations, combined with an improved understanding of the molecular biology of the disease provide leads to explore testable PCa prevention strategies. Current treatment strategies such as hormone therapy, radiation and surgery are proving useful in reducing the mortality associated with PCa, however, malignant and non-malignant tumors continue to progress and become refractory to these treatment options. Although, these treatments provide a limited success in reducing the mortality in PCa patients, the severe side effects of these treatments have also been reported. These include rectal complications, urinary incontinence, and impotence, loss of libido, weight gain, gynaecomastia, liver inflammation, and osteoporosis^[11]. Because PCa is a complex process that involves different molecular events, usually occurring simultaneously, blocking or inhibiting only one event will not be sufficient to pre-

vent or delay the onset of the disease. It is therefore necessary to intensify our efforts for a better understanding of PCa pathophysiology, and for the development of novel approaches for its prevention and treatment. Among many preventive approaches chemoprevention through the use of non toxic dietary substances is gaining popularity^[12,13].

Many types of natural agents that act on various molecular targets have been reported to inhibit or delay various stage(s) of cancer^[12,13]. Epidemiological studies have shown a correlation between populations with higher consumption of selenium and vitamin E, fruits and tomatoes, in lowering the risk of PCa^[14,15]. Consistent with this notion, several single natural agents are currently being studied for their potential as preventive agents against PCa. Tea derived from the plant *Camellia sinensis*, has been studied extensively and shown to have anti-mutagenic and anti-cancer effects in animal tumor models^[16,17]. In 1999, we initiated a program to assess whether tea consumption could afford chemopreventive effects against prostate carcinogenesis^[18], which we continue to pursue. This research has also been extensively followed in many laboratories around the world. In this review we summarize the laboratory studies, clinical trials and epidemiological observations supporting the use of tea or its individual constituent polyphenols in prevention and/or better management of PCa.

Chemoprevention and prostate cancer

The magnitude of the problem of cancer and the failure of conventional strategies to effect a marked diminution in the total number of deaths from this disease now indicate that other preventive or therapeutic measures should be

seriously explored. Many strategies are possible to reduce cancer-related deaths, four of which are noteworthy: (1) prevention; (2) early diagnosis and intervention; (3) successful treatment of localized cancer; and (4) improved management of non-localized cancer. Among these, prevention appears to be the most practical approach. One approach for preventing the occurrence of cancer(s) is through chemoprevention. Chemoprevention, by definition, *is a means of cancer control in which the occurrence of the disease can be entirely prevented, slowed or reversed by the administration of one or more naturally occurring and/or synthetic compounds*^[19–23]. This approach is promising because therapy and surgery have not been fully effective against the high incidence and/or low survival rate of most cancer types. Furthermore, this approach with the use of dietary substances appears to have practical implications in reducing cancer risk because unlike the carcinogenic environmental factors that are difficult to control, individuals can make decisions to modify the food and beverages they consume.

Chemoprevention, especially through consumption of tea, appears to be a useful strategy for the management of PCa. This is well-supported by the epidemiological observation that the Japanese and Chinese populations, which are habitual drinkers of several cups of tea, have one of the lowest rates of PCa in the world^[24]. PCa is believed to be an ideal candidate disease for chemoprevention because of its high latency period and because it is typically diagnosed in men over the age of 50. Thus, even a slight delay in the progression of this disease by chemoprevention could result in substantial reduction in the incidence of the disease and more importantly, improve the quality of life of the patients with the disease^[25,26]. If chemoprevention delays the clinical course of PCa even by 5 years, the incidence of and deaths from this disease would decrease substantially^[27]. The identification of promising agents (and their molecular targets) for PCa prevention is guided by data derived from a variety of sources. These evidence-based leads come from (1) epidemiological observations; (2) PCa clinical trials; (3) secondary analyses from large, randomized, controlled cancer clinical trials; (4) understanding the mechanism of prostate carcinogenesis; and (5) experimental animal models.

Tea: an overview

Tea, made from the leaves of *Camellia sinensis*, an ever-green shrub of the *Theaceae* family, is a beverage of choice in many countries around the world. The first instance of tea drinking dates back to 2737 BC. According to a Chinese legend, it was Emperor Shen Nung of China who accidentally

discovered the refreshing effects and fine taste of tea when he was out camping and a few leaves of a tea plant fell into his cup of boiling water. Currently tea plant is cultivated in approximately 30 countries. Based on the method of processing, tea is typically of three types: black, green and oolong. Black tea, predominantly consumed in Western and some Asian countries, shares a major part of world tea production, accounting for about 78% of total tea consumption. About 20% of the total tea manufactured is green tea, and is mainly consumed in China, Japan, India, and a few countries in North Africa and the Middle East. The remaining 2% of tea consumed is oolong tea, mainly produced and consumed in southeastern China.

Tea contains several polyphenolic components, which are antioxidative in nature, and many studies have shown that tea polyphenols possess the ability to prevent oxidant-induced cellular damage^[28,29]. In recent years, studies from ours and many laboratories around the world, conducted in various organ-specific animal bioassay systems, have shown that tea and its polyphenolic constituents are capable of affording protection against a variety of cancer types^[13,16,19,29]. Although most of the studies conducted have used green tea, a limited number of studies have also shown the anti-cancer efficacy of black tea.

Tea as a beverage is consumed worldwide at greatly varying levels. Not only does tea consumption vary from country to country, but also there is enormous variation within a given population. This ranges from no tea to as many as 20 or more cups per day. Although definite data are not available, it is generally accepted that next to water, tea is the most consumed beverage in the world; with a per capita worldwide consumption of approximately 120 mL per day^[30].

The composition of tea-leaf varies with climate, season, horticultural practices, variety of the plant, and the position of the leaf on the harvested shoot (ie, its age). The composition of different types of teas varies according to the manufacturing process, which differs in the degree of 'enzymatic oxidation' or fermentation. Thus, green tea is unfermented, oolong tea is partially fermented, and black tea is fully fermented. Table 1 shows the principal polyphenolic components present in a typical green and black tea beverage, but variations may be considerable. Oolong tea composition in general falls between that of green and black teas^[31].

Polyphenols of tea

Tea leaves are quite unique in that they are a rich source of catechins, theanine and methylxanthines (Table 1). The chemical composition of green tea is more or less similar to that of the fresh leaf with regard to the major components.

Table 1. Polyphenolic composition of green and black tea (%).

CONSTITUENTS	GREEN TEA	BLACK TEA
Catechins	30–42	3–10
Flavonols	5–10	6–8
Other flavanoids	2–4	–
Theogallin	2–3	–
Gallic acid	0.5	–
Quinic acid	2.0	–
Theanine	4–6	–
Methylxanthines	7–9	8–11
Theflavins	–	3–6
Thearubigins	–	12–18

Green tea contains polyphenolic compounds, which include flavanols, flavandiols, flavonoids, and phenolic acids. These compounds account for up to 30% of the dry weight of green

tea leaves. Most of the polyphenols present in green tea are flavanols, commonly known as catechins. Some major catechins present in green tea are (-)-epicatechin (EC), (-)-epicatechin-3-gallate (ECG), (-)-epigallocatechin (EGC), and (-)-epigallocatechin-3-gallate (EGCG). The chemical structures of these compounds are given in Figure 2. In addition, caffeine, theobromine, theophylline, and phenolic acids such as gallic acids are also present in green tea (Table 1). Green teas are generally produced in two different varieties; white tea and yellow tea, the latter is less fermented because of a process known as wilting. In the production of black and oolong tea, fresh leaves are allowed to wither until the moisture content of the leaves is reduced to about 55% of the original leaf-weight resulting in the concentration of polyphenols and the deterioration of leaf-structural integrity. The withered leaves are rolled and crushed, initiating fermentation of the polyphenols. This process is known as maceration. During these processes the catechins are converted to

Figure 2. Chemical structures of major green and black tea polyphenols. R = galloyl group.

theaflavins (TF) and thearubigins. TF are astringent compounds contributing importantly to color and taste of black tea. The thearubigen fraction is a mixture of substances, with a molecular weight distribution of 1 000–40 000 and account for 15% of dry weight solids of black tea. Oolong teas are prepared by firing the leaves shortly after rolling to terminate the oxidation and drying the leaves. Normal oolong tea is considered to be about half fermented compared to black tea. Oolong tea extracts contain catechins at a level of 8%–20% of the total dry matter.

During the fermentation process involved in the manufacture of black tea, the monomeric flavanols undergo polyphenol oxidase-dependent oxidative polymerization leading to the formation of bisflavanols, TF, thearubigins, and some other oligomers. TF (1%–2%, on dry weight basis) contains benzotropolone rings with dihydroxy or trihydroxy substitution systems. About 10%–20% of the dry weight of black tea is due to thearubigins, which are even more extensively oxidized and polymerized. The structures of TF and thearubigins are shown in Figure 2. Oolong tea contains monomeric catechins, TF, and thearubigins. In addition, epigallocatechin esters, theasinensins, dimeric catechins, and dimeric proanthocyanidins are also the characteristic components of oolong tea.

Biochemical properties of tea and its polyphenols

Tea is consumed worldwide for a variety of reasons from improving blood flow, eliminating toxins and improving resistance to various diseases and combating two of the greatest killers of human population: cancer and cardiovascular diseases. Supportive scientific evidence for these claims, based on the data generated in recent times have lead to an increase in consumption of green tea. The most widely recognized biological properties of tea polyphenols are the antioxidant properties^[30,32]. Studies have shown that tea or EGCG can lower lipid absorption and plasma lipid levels in rats^[33], increase high-density lipoprotein cholesterol in humans^[34] and decrease blood glucose^[35,36]. The health beneficial effects of tea and its polyphenols have been summarized recently in a review from our laboratory^[30].

Several studies have suggested that the polyphenols, present in tea possess high antioxidant activities, which in turn, protects cells against the adverse effects of damaging reactive oxygen species (ROS) such as superoxide radical, hydroxyl radical, singlet oxygen, hydrogen peroxide, peroxynitrite, and alkoxyradicals that are constantly produced in the body. These ROS damage lipids, proteins, nucleic acids, and cellular components such as ion channels,

membranes, and chromatin leading to cellular injury and cellular dysfunctions and thus contribute to the etiology of many chronic health problems including inflammatory diseases, diabetes, obesity, cancer and cardiovascular diseases^[29,30,37,38]. Studies in culture systems have shown that both green tea extract and EGCG are capable of inhibiting the growth of a variety of mouse and human cancer cell types^[13,19,30]. Ahmad *et al*^[39] initially reported these effects showing that green tea polyphenol (GTP) may protect against cancer by causing cell cycle arrest and inducing apoptosis in various carcinoma cells without affecting normal cells.

Some of the effects of tea polyphenols may also be due to the chelation of metal ions. Because of its chelating properties, tea may additionally protect against toxicity due to heavy metals. Tea manifests chelating activity *in-vivo* as indicated by the fact that tea consumption lowers absorption of dietary iron in controlled feeding studies and decreases body iron balance^[40]. This study had also shown that EGCG may chelate cations, which contribute to its ability to inhibit angiotensin-converting enzyme. Tea polyphenols chelate copper ions and this mechanism has also been suggested to protect low-density lipoproteins from peroxidation^[41]. Catechins may also affect signal transduction pathways, modulate many endocrine systems, and alter hormones and other physiological processes as a result of their binding these metals and enzyme co-factors^[42]. Tea polyphenols have been shown to inhibit the activation of transcription factors AP-1 and NF- κ B and synthesis of nitric oxide^[43–46]. Inhibition of cell transformation and cell growth by purified catechins and TF has been reported^[47]. These activities have been attributed to the inhibition of AP-1 activity, possibly due to the inhibition of several steps of signal transduction pathways [eg, mitogen-activated protein kinase (MAPK) activities by tea polyphenols]^[48]. It has been reported that tea and its polyphenolic constituents impart inhibitory effects on the activities of many enzymatic and metabolic pathways relevant to cancer development^[49].

Tea and its constituents in the management of PCa

For many years the concept of management of PCa by means of dietary intervention has been the subject of increasing attention and discussion^[50]. Epidemiological studies show that in Asian populations that consume tea, the incidence of all types of cancer including PCa is low compared to that in the West^[3,8,24,51,52]. Thus, it has been suggested that the low occurrence of PCa in Asian countries may be due, in part, to the consumption of green tea by these populations.

In the year 1999, our laboratory initiated a program to assess the effect of tea consumption on prostate carcinogenesis. Because the role of the androgen-responsive gene, ornithine decarboxylase (ODC), the key regulatory enzyme in the biosynthesis of polyamine is well documented in carcinogenesis^[53], we analyzed ODC activity in paired benign and cancer tissues obtained from same individual with PCa and found that ODC activity in cancer tissue was 2.7-fold higher than in the corresponding paired benign tissue. This exciting observation suggested that ODC could be extrapolated as a target for prevention and therapy of PCa. Extending these studies we investigated the effect of the polyphenolic fraction isolated from green tea (GTP) against testosterone-mediated induction of ODC in (1) LNCaP cells; (2) Cpb: WU rats; and (3) C57BL/6 mice; and found that GTP resulted in a significant reduction in testosterone-mediated induction of ODC activity in the prostate^[18]. We then reasoned that these studies should be extrapolated and GTP should be able to inhibit PCa development in an appropriate animal model of PCa. Transgenic adenocarcinoma of the mouse prostate (TRAMP) is one such model for PCa that closely mimics progressive forms of the human disease^[54]. In this model, we provided convincing evidence that oral infusion of GTPs (equivalent to 6 cups of green tea consumption in humans) inhibits prostate carcinogenesis^[55,56]. The outcome of this study was later verified by Caporali and colleagues who demonstrated that GTC significantly inhibited PCa development in TRAMP mice^[57]. This study further demonstrated that in TRAMP mice, the clusterin gene was dramatically downregulated during onset and progression of PCa. In the GTC-treated TRAMP mice in which tumor progression was chemoprevented, clusterin mRNA and protein progressively accumulated in the prostate gland. The clusterin levels returned to undetectable levels in animals in which GTC chemoprevention failed and PCa developed.

Below, we summarize the biological activities of tea and its constituents in relation to PCa.

Effect of tea polyphenols on androgen synthesis and androgen receptor Because androgens are capable of both stimulating proliferation as well as inhibiting the rate of glandular epithelial cell death within the prostate, androgen ablation therapy is commonly suggested for men with this non-organ confined disease^[58]. Huggins *et al* for the first time demonstrated the use of androgen deprivation as a treatment for advanced PCa^[59]. Since then removal of androgenic stimulation has been used to treat this disease. Kao *et al*^[42] reported that treatment with EGCG (85 mg/kg body weight) for 7 d reduces the circulating testosterone levels by 70% in a murine model that can be associated with the lower-

ing of PCa risk. Studies that followed have shown that tea polyphenols might block the pathway that leads to the synthesis of androgen. Populations with impaired androgen metabolism such as hereditary 5 α -reductase deficiency do not develop PCa, while those with higher circulating levels of androgen are at a higher risk of the disease^[60]. In tumor xenograft studies of PCa, the 5 α -reductase inhibitors were found to slow the growth of previously established tumors^[61]. It has been reported that green tea constituents, EGCG and ECG, inhibit the activity of type 1 rat 5 α -reductase^[62]. These polyphenols also inhibited types 1 and 2 human 5 α -reductase in microsomes from rat cells that expressed the human enzyme. Several molecular mechanisms have been postulated to be accountable for the development of sporadic hormone-refractory tumors. Most of these mechanisms involve alterations in the function of the androgen receptor (AR) and its complex signaling pathways^[63]. Several studies have demonstrated that AR is expressed in all of the stages of PCa, and at least one-third of advanced PCa contain amplified AR genes^[64-66]. It is suggested that overexpression or mutation of the AR in PCa cells may promote a growth advantage. Therefore, it has been of great interest to seek more effective means of minimizing or eliminating the function of the AR in order to achieve preventive and/or therapeutic treatments for prostatic neoplastic disease. One study reported that tea polyphenols downregulated the expression of the AR in androgen responsive to LNCaP prostate carcinoma cells^[67]. They reported a significant reduction in AR mRNA by the EGCG treatment. The basal activity of the AR promoter is determined by an Sp1 binding site within the AR core promoter region^[68,69]. Sp1 not only regulates the basal expression of the AR but also acts as its coregulator^[70]. Sp1 is involved in the expression of genes related to cell proliferation^[71]. Since Sp1 regulates the expression of many critical genes, the decrease in this protein by tea polyphenols could somewhat decrease the growth rates of prostatic cells. EGCG has been reported to significantly decrease the Sp1 DNA binding activity^[67]. However additional work is necessary to authenticate the effect of tea constituents on androgen synthesis or its receptor status in a manner that could lead to protection against development of PCa.

Effect of tea polyphenols on prostate specific antigen Prostate specific antigen (PSA) is a glycoprotein secreted by the prostate gland. Functionally, PSA is a kallikrein-like serine protease produced by the epithelial cell lining of the acini and ducts of the prostate gland^[72]. It circulates in the serum in both free (unbound) and complex forms. The most common cause for an elevated serum PSA

is benign prostatic hyperplasia, the incidence of which increases with age, similar to PCa. Reduction in serum PSA levels has been proposed as an endpoint biomarker for staging hormone-insensitive human PCa intervention. At present, the measurement of serum PSA levels is the most commonly used biomarker for monitoring the progression of PCa and the response to therapy^[66]. It has been suggested that serum PSA levels can be decreased by the agents that lower serum testosterone levels such as leutinizing hormone releasing hormone agonists and antagonists, anti-androgens such as flutamide and bicalutamide, and the 5 α -reductase inhibitors such as finasteride^[73,74]. We evaluated the effect of EGCG on the production of PSA in androgen-sensitive human prostate carcinoma LNCaP cells. This study demonstrated that EGCG treatment resulted in significant dose-dependent decrease in PSA level in the culture medium. Further, a significant time-dependent decrease in PSA production was also observed after EGCG treatment compared with the control. The validity of these cell culture observations to human PCa patients could have implications in reducing PCa body burden. Therefore, clinical data where PSA levels are being monitored after administration of green tea to PCa patients could be of interest.

Polyamine synthesis and tea polyphenols Polyamines are present in all living cells and are essential for cell differentiation, proliferation^[75] and migration^[76]. Depletion of polyamines results in the inhibition of cell proliferation and migration and the failure of embryonic development, whereas accumulation of polyamines causes apoptosis^[77,78] or cell transformation^[79,80]. Cells maintain intracellular polyamines at optimal levels by regulating synthesis or degradation and by uptake or release of polyamines from or to the exterior. Prostate tissue is known to contain some of the highest concentrations of polyamines and polyamine-metabolizing enzymes in the body^[81,82]. ODC is a key regulatory enzyme for polyamine synthesis and the induction of its activity has been reported to be linked with various types of cancers including PCa^[53,83–85] and thus, ODC has been used as a biomarker for the chemopreventive studies^[86]. An induction in the ODC activity and ODC mRNA expression mediated by testosterone has been reported in prostate carcinoma cells^[87,88]. Our laboratory reported that GTPs significantly reverse the induction of ODC activity as well ODC mRNA expression in LNCaP cells^[18]. We also demonstrated that testosterone when administered to the C57 BL/6 mice, caused a 2-fold increase in ODC activity in the ventral prostate while prior oral infusion of 0.2% (w/v) GTP in drinking water resulted in 40% inhibition in this induction. In a recent study EGCG was shown to decrease both tumor number and total

tumor burden compared with untreated ODC/Ras mice without decreasing the elevated polyamine levels present in the ODC/Ras mice^[89].

Tea polyphenols and gene expression Cancer is believed not to be a single disease but rather a conglomeration of several diseases and several genes are known to play imperative roles at various stages and at different levels in it. These include the genes that regulate growth, cell signaling, differentiation, cell death, cell division and cell migration. There is always an upregulation or suppression of such genes in the process of cancer development. Tea polyphenols have been shown to modulate the function of various genes at various levels. We identified nine genes, including six kinases and three phosphatases, whose expression was found to be downregulated by EGCG^[90]. The genes repressed by EGCG mostly belonged to the G-protein signaling network and are responsible for cell proliferation, and include adenosine kinase, protein kinase C α (PKC- α) and type I β cGMP-dependent protein kinase. Interestingly, the PKC- α form, whose inhibition of expression has been shown to inhibit cell growth in some cancer cells, was selectively repressed by EGCG while the expression of six other PKC isoforms (β , δ , ϵ , μ , η and ζ) was unaffected^[90]. PKC is known to be involved in several diverse cellular functions including cell differentiation, growth control, tumor promotion and progression and cell death. It is also a regulator of cell cycle events during G1 progression and G2/M transition. Inhibition of PKC- α gene expression is believed to inhibit cell proliferation in the animal tumor model and in some human cancer cell lines. We have shown that EGCG inhibits the expression of the PKC- α gene, adenosine kinase and type I β cGMP-dependent protein kinase in LNCaP cells and hence is able to block the intracellular cyclic-nucleotide signaling cascade^[90].

The loss of tumor suppressor genes and the genes producing anti-growth factors is an important event in cancer development. Studies have shown that EGCG induces the expression of 16 kinases and phosphatase genes in prostate cells. These include tumor suppressor gene SHP-1 and the genes that produce pyrroline-5-carboxylate and prostatic acid phosphatase. The p53 tumor suppressor gene is the most frequently mutated gene found in human malignancies, including cancer of the prostate gland. Generally, no correlation between p53 mutation and early stage PCa has been noticed but p53 mutations are shown to be associated with 10%–20% of advanced PCa patients with high Gleason grade and distant site metastasis^[91,92]. In a study from our laboratory, we have shown that EGCG upregulated the protein levels of p53 in LNCaP cells (with wild type p53) but not

in DU 145 cells (with mutant p53)^[93]. Further, we have also shown that EGCG-induced apoptosis in LNCaP cells occurs through the stabilization of p53 protein via phosphorylation on critical serine residues and p14^{ARF}-mediated downregulation of MDM2 protein^[94].

Role of tea polyphenol on programmed cell death (apoptosis) in PCa Morphologically, apoptosis is characterized by a temporal sequence of events consisting of chromatin aggregation, nuclear and cytoplasmic condensation, and eventual fragmentation of the dying cell into a cluster of membrane bound segments that often contain morphologically intact organelles^[95]. These apoptotic bodies are rapidly recognized, phagocitized, and digested by either macrophages or adjacent epithelial cells^[96]. The hallmark of apoptosis is the fragmentation of genomic DNA, an irreversible event that commits the cell to die and occurs before changes in plasma and internal membrane permeability^[97]. In addition, apoptosis is a discrete way of cell death that is different from necrotic cell death and regarded to be an ideal method of cell elimination^[98]. Under normal cellular situations a balance between cell growth and cell death is maintained, this balance is lost in favor of cell growth in the case of cancers including cancer of the prostate gland. Correction of this imbalance could lead to the prevention and even ablation of prostatic cancer^[99,100] as apoptosis is closely involved in the initiation, progression, and metastasis of human PCa. Since human PCa represents a heterogeneous mixture of androgen-dependent and androgen-independent mixture of cells, the surgery and chemotherapy have failed to address this problem. Hence, one potential strategy to eradicate this mixture of cells is to modulate the apoptotic machinery by chemopreventive agents. Chemopreventive agents, which can modulate apoptosis, may be able to affect the steady-state cell population that can be useful in the management and therapy of cancer. Many cancer chemopreventive agents have been shown to induce apoptosis and conversely several tumor promoters have also been shown to inhibit apoptosis^[101–103]. Therefore, it is reasonable to assume that the chemopreventive agents that have proven effects in animal tumor bioassay systems and/or human epidemiology on one hand and cause induction of apoptosis of cancer cells on the other hand may have wider implications for cancer control. Studies from this and other laboratories have shown that EGCG results in an induction of apoptosis in several human carcinoma cells^[39,93,104]. A study from our laboratory has demonstrated that green tea constituent EGCG results in an induction of apoptosis in human PCa cells LNCaP and DU145^[93]. This observation was subsequently verified by the studies from another laboratory^[105]. We

recently demonstrated that EGCG-induced apoptosis in human prostate carcinoma LNCaP cells is mediated via modulation of two related pathways: (1) stabilization of p53 and down regulation of MDM2 protein; and (2) negative regulation of NK- κ B activity, thereby, decreasing the expression of the pro-apoptotic protein Bcl-2^[94].

Role of tea polyphenols on angiogenesis in PCa Cancer cells move from their original sites and invade surrounding tissues, a phenomenon known as ‘metastasis’. Metastasis is subsequently followed by the formation of new blood vessels, a phenomenon known as ‘angiogenesis’, a major event of later stages of carcinogenesis. Some hydrolases and matrix metalloproteases (MMPs) have been reported to be overexpressed during the invasion of cancer cells and angiogenesis^[106,107]. Once tumors become aggressive and start to metastasize to other organs, even systemic chemotherapy may be futile. Garbisa *et al*^[108] reported that EGCG is a potent inhibitor of gelatinases and an orally available pharmacologic agent that may confer the antiangiogenic and antimetastatic activity associated with green tea. EGCG was also found to inhibit tumor cell invasion and directly suppress the activity of two matrix metalloproteases, MMP2 and MMP9, most frequently overexpressed in cancer and angiogenesis and essential in penetrating the basement membrane barriers^[109–111]. Recently we showed that green tea infusion in the TRAMP mice resulted in marked inhibition of the markers of angiogenesis and metastasis most notably vascular endothelial growth factor (VEGF), urokinase plasminogen activator (uPA), and MMPs 2 and 9^[112]. It has been shown that tea components slow the progression of LNCaP human prostate tumors in SCID mice, partly by inhibiting the formation of new blood vessels^[113]. A recent study investigated the effect of EGCG on the tube formation of human umbilical vein endothelial cells (HUVEC) on matrigel. Tube formation was inhibited by treatment both prior to plating and after plating endothelial cells on matrigel with EGCG. EGCG treatment also was found to reduce the migration of endothelial cells in a matrigel plug model. These findings suggest that EGCG also acts as an angiogenesis inhibitor by modulating protease activity during endothelial morphogenesis^[110].

Role of tea polyphenols on Insulin like growth factor in PCa Studies established that elevated circulating levels of Insulin-like growth factor 1 (IGF-1) are associated with increased risk of several common cancers, including those of the breast, prostate, lung and colorectum^[114]. IGF-1 has mitogenic and anti-apoptotic effects on prostate epithelial cells *in vitro* and has been strongly implicated in the etiology of human PCa. The level of IGF-binding protein 3 (IGFBP-3), a major IGF-1 binding protein in serum that, in most

situations, suppresses the mitogenic action of IGF-1, has been shown to be inversely associated with the risk of different cancers^[115]. The elevated level of IGF-1 with concomitant lowering of IGFBP-3 in serum is an excellent predictor of PCa progression in humans. The identification of agents that can inhibit the IGF-1 signaling pathway could lead to the development of highly successful prevention strategies for PCa. IGF-1 has been implicated as an important factor in the initiation and progression of PCa in a TRAMP model^[116], and we have shown that oral infusion of GTP significantly lowers IGF-1 levels and restores the depleted levels of IGFBP-3 in the serum of TRAMP mice^[55]. In a study, we demonstrated that the IGF-1/IGFBP-3 signaling pathway is a prime pathway for GTP-mediated inhibition of PCa that limits the progression of cancer through inhibition of angiogenesis and metastasis^[112].

Regulation of cell cycle in prostate cancer cells by tea polyphenols The mammalian cell division cycle is a set of events that governs the self-replication of cells. Normal cell growth and division depends on precise regulation of cell cycle; the loss of which can result in unrestrained cell division. The consequence of this includes cell proliferation, tumorigenesis and cancer. A controlled cell cycle progression is important and essential for normal tissue homeostasis^[98]. Cell cycle progression is monitored by surveillance mechanisms, or cell cycle checkpoints, that ensure initiation of a later event is coupled to the completion of an early cell cycle event. One or more cell-cycle checkpoint defects are involved in most of the cancer types including PCa^[93,117,118]. A normal cell cycle progression is dependent on the ability of the cell to translate extracellular signals, such as mitogenic stimuli and intact extracellular matrices in order to efficiently replicate DNA and divide. The cell cycle progression is controlled by kinase complexes consisting of a cyclin-dependent kinase (Cdk) subunit and a cyclin subunit. Cdk respond to the extracellular signals and push cells through the cell cycle. Transitions between different phases in the cell cycle are driven by sequential activation and inactivation of various Cdk in complexes with cyclins. Abnormal Cdk activity is accomplished by cyclin amplification, cdk or substrate mutation as well as inactivation of inhibitors such as WAF1/p21, INK4a/p16, and INK4c/p18^[120]. The selective growth advantage of cancer cells also stems from the amplification of positive growth signals and mutation of checkpoints. The loss of cell cycle checkpoints results in the selection of cells that have a growth advantage that may result in drug resistance, invasion and metastasis^[121]. Also, inhibition of the cell cycle has been appreciated as a target for the management of cancer^[122]. A few reviews are avail-

able that contain information about the dysregulation of cell cycle in prostate carcinogenesis^[118,119]. Tea polyphenols have been shown to impart cell cycle arrest in cancer cells via inducing the expression of cdk inhibitors^[123]. Earlier, our laboratory showed that EGCG exhibited a dose-dependent arrest of cells in G0/G1 phase of the cell cycle, thereby slowing the growth of human PCa cells^[93]. Recently, we elucidated the molecular mechanism involved in the cell cycle arrest in human PCa cells^[123]. Our data demonstrated that EGCG treatment of LNCaP and DU-145 cells resulted in significant dose- and time-dependent (1) upregulation of the protein levels of WAF1/p21, INK4a/p16, and INK4c/p18; (2) down-modulation of the protein levels of cyclin D1, cyclin E, cdk2, cdk4, and cdk6, but not of cyclin D2; and (3) increase in the binding of cyclin E toward cdk2. This resulted in a blockade of G1 to S transition, causing a G0/G1 phase arrest of the cell cycle. The effect of EGCG on the interbinding between the different components of the cki-cyclin-cdk network, however, needs further investigation.

Modulation of phosphatidylinositol-3-kinase/protein kinase B and mitogen activated protein kinases by tea Phosphatidylinositol-3-kinase (PI3K)/protein kinase B (PKB) and MAPK signaling pathways are regarded to play a critical role in cellular proliferation, cell cycle regulation and apoptosis. Defects in these signaling pathways have been found to result in the development of various cancer types^[124]. PI3K catalyzes the formation of the 3'-phosphoinositides, phosphatidylinositol 3,4-diphosphate and phosphatidylinositol 3,4,5-triphosphate. An increase in 3'-phosphoinositides leads to membrane translocation of downstream effectors such as the serine/threonine protein kinase Akt, resulting in increased cellular proliferation and protection from apoptosis^[125]. The MAPK family such as extracellular signal regulated protein kinase (Erk) 1 and 2 are shown to be constitutively active in PCa in humans, and possibly play a causative role in the progression of this malignancy from an androgen-sensitive phenotype to an advanced and androgen-insensitive metastatic disease. It has been shown that the activation of MAPK by green tea might be a potential mechanism in the regulation of antioxidant-responsive element mediated phase II enzyme gene expression^[126]. In one report, the authors found that GTP causes a significant activation of extracellular signal-regulated kinase 2 (ERK2) and c-Jun N-terminal kinase 1 (JNK1)^[126]. GTP treatment also resulted in increased mRNA levels of the immediate-early genes c-jun and c-fos, as determined by reverse transcriptase-coupled polymerase chain reaction^[126]. Exposure of normal human epidermal keratinocytes (NHEK) to UVB radiation induces oxidative stress and phosphorylation of

MAPK. Studies from this laboratory have shown that pretreatment of normal NHEK with EGCG inhibits UVB-induced H₂O₂ production and H₂O₂-mediated phosphorylation of MAPK^[127].

We recently evaluated the effects of EGCG and TF, on PI3K- and MAPK-pathways in DU145 and LNCaP cells. Both EGCG and TF treatment were found to (1) decrease the levels of PI3K and phospho-Akt; and (2) increase Erk1/2 in both DU145 and LNCaP cells. This study, for the first time, demonstrated the modulation of the constitutive activation of PI3K/Akt and Erk1/2 pathways by EGCG as well as TF^[124]. More recently an *in vivo* study revealed that oral infusion of GTP resulted in significant decrease in (1) the protein levels of PI3K; (2) phosphorylation of Akt; and (3) phosphorylation of ERK1/2 in TRAMP^[112].

Modulation of nuclear factor κ B by EGCG The nuclear transcription factor NF- κ B plays an important role in inflammation, autoimmune response, cell proliferation and apoptosis by regulating the expression of genes involved in these processes and thus, is widely recognized as a critical mediator of immune and inflammatory responses. Constitutive activation of the transcription factor NF- κ B has been observed in a high proportion of androgen-independent PCa^[128–130]. In addition to suppressing apoptosis, NF- κ B promotes malignant behavior in other ways like stimulating transcription of cell cycle progression factors (c-myc, cyclin D1), proteolytic enzymes (MMP-9, uPA), and angiogenic factors VEGF and IL-8^[130,131]. Thus, it is not surprising that nuclear localization of NF- κ B in PCa biopsies has been shown to correlate with poor clinical prognosis^[132]. A mystifying array of natural products, some of which have putative chemopreventive activity, are reported to inhibit constitutive and/or stimulated NF- κ B activity in human PCa. In a study, we demonstrated that EGCG treatment to normal NHEK keratinocytes resulted in a significant dose- and time-dependent inhibition of UVB-mediated activation and nuclear translocation of a NF- κ B/p65, suggesting that that EGCG protects against the adverse effects of UV radiation via modulations in the NF- κ B pathway^[46]. In another study from our laboratory, it was demonstrated that EGCG had a concurrent effect on p53 and NF- κ B, causing a change in Bax/Bcl-2 ratio in a way that favors apoptosis in prostate carcinoma LNCaP cells^[94].

Effects of tea and its polyphenols on prostate tumor xenografts Athymic nude mice implanted with tumor xenografts have been widely used as an established pre-clinical *in vivo* model to assess the effect of drugs and/or synthetic agents and dietary substances on the development of a variety of cancer types. Liao and colleagues^[133]

studied the effects of tea polyphenols on growth inhibition and regression of prostate tumors in athymic nude mice. They found that intraperitoneal injection of EGCG but not structurally related catechins, such as ECG, inhibited the growth and rapidly reduced the size of human prostate PC-3 (androgen-insensitive) and LNCaP 104-R (androgen-repressed) tumors. In a recent study^[134], we demonstrated that GTP, black tea extract (BTE), EGCG and TF resulted in significant inhibition in the growth of androgen responsive CWR22Rv1 implanted tumors in athymic nude mice. Further, treatment of mice with all tea preparations resulted in significantly reduced PSA secretion in serum measured at 3 and 4 weeks post implantation of CWR22Rv1 cells. The immunoblot analyses of the tumors revealed that the prostate tumor growth inhibitory response of all tea preparations was accompanied with (1) decrease in Bcl-2 (anti-apoptotic) with a concomitant increase in Bax (pro-apoptotic); (2) activation of Caspase-3; (3) cleavage of PARP; and (4) decrease in VEGF. This study suggested that GTP and BTE as well as their major polyphenolic constituents EGCG and TF significantly inhibited the development of PCa via (1) induction of apoptosis; and (2) inhibition of angiogenesis in tumors. Furthermore, in an independent experiment, we found that GTP, at very low doses (0.1% and 0.05% in water) resulted in a significant regression of tumors in athymic nude mice when given after CWR22Rv1 tumors were established to a volume of approximately 400 mm³. These data point to a potential therapeutic benefit of black as well as green tea against PCa.

Custom tailoring of chemopreventive regimen for prostate cancer

Cancer is the result of several genetic mutations, which in turn results in defects in multiple signaling pathways being affected. It is therefore unlikely that any single agent may prove to be totally effective and/or beneficial for PCa prevention or treatment in all populations on a long-term basis. We recently advocated the idea of combining naturally occurring agents in a manner that could be more beneficial and at the same time would not exhibit toxicity. It is of interest that several dietary agents that are effective chemopreventive agents in one experimental setting can enhance or have no effects on carcinogenesis in another experimental setting. Thus it is likely that we can custom tailor or personalize the chemopreventive regimen through a cocktail of agents with agents that have known mechanisms targeted for different individual needs. This concept of combining chemopreventive agents to achieve greater benefits is being increasingly appreciated and studies are being con-

ducted in our and other laboratories using a combination of natural agents and chemotherapeutic drugs. To achieve the objective, there is also a need to understand genetic, environmental, and lifestyle factors that influence various populations for whom the chemoprevention intervention is considered. This information could be critical in the selection of an appropriate cancer chemopreventive regimen for individuals with varying risk for PCa development. A combination of different nutraceuticals with varied mechanisms of action could be more effective as they could attack process of carcinogenesis at more than one site or pathway(s) and result in the treatment having an additive or synergistic effect against cancer growth and development. We recently demonstrated the combined inhibitory effects of green tea polyphenols and COX-2 inhibitor on growth of PCa cells in *in-vivo* and *in-vitro* situations^[135]. This study reported an increased efficacy of selective COX-2 inhibitors in combination with polyphenols from green tea for inhibition of growth of human prostate cancer cells both *in vitro* and *in vivo*. A recent study demonstrated that combined treatment with lycopene and vitamin E, at 5 mg/kg BW each, suppressed orthotropic growth of PC-346C prostate tumors by 73% and increased median survival time by 40%^[136]. In another study, Venkateswaran *et al.* demonstrated that selenium potentiates vitamin E-induced inhibition of LNCaP cells and this inhibition was demonstrated by a reduction of cells in the S-phase of cell cycle^[137]. A study by Tokar *et al.*^[138] examined the effects of synthetic retinoid N-(4-hydroxyphenyl) retinamide (4-HPR) in combination with cholecalciferol (vitamin D3) on growth, and on the expression of vimentin, matrix metalloproteinase-2 (MMP-2), and retinoid and vitamin D receptor expression, using the non-tumorigenic, human prostate epithelial cell line RWPE-1. These results suggested that combined treatment with 4-HPR and cholecalciferol, at doses lower than what might be effective with single agents, increase anti-cancer efficacy.

In light of the observations suggesting more beneficial effects with a combination of chemopreventive agents at low doses, we advocate to design experiments containing a mixture of substances that target multiple signaling pathways.

Epidemiological studies

In recent years, the availability of increasingly sophisticated biochemical approaches of molecular epidemiology has made the process of cancer formation easier to understand and comprehend. Such understanding has offered opportunities for defining the risk to individuals and for modulating this risk by means of agents that can alter critical steps in the

multistage process of carcinogenesis. As of yet, only a few case control studies have been conducted to evaluate the effect of consumption of tea for human PCa. All published data seeking an association between tea consumption and the risk of PCa considered undefined tea preparations, mostly black tea. The possible harmful effects of excessive tea consumption, tea consumption at very high temperature, or the consumption of salted tea had not been yet ruled out. Two epidemiological studies have shown that people who regularly consume tea have a lower incidence of PCa^[139,140]. Heilbrun *et al.*^[139], in a prospective cohort study of 7833 men living in Hawaii with Japanese ancestry, observed a weak but significant negative association between black tea intake (more than one cup per day) and PCa incidence ($P=0.02$). In a case-control study conducted in 3 geographical areas of Canada, Jain *et al.*^[140] observed a decrease in PCa risk with an intake of more than 2 cups of tea per day. Other epidemiological studies conducted in Italy^[141], Utah^[142] and Canada^[143] did not find any difference of risk for PCa between tea drinkers and non-drinkers. It should be noted that most of these studies lacked appropriate controls for comparison in categorization of tea consumption, the type of tea consumed and the ethnicity of the subjects, which weakens the overall effect of the study.

Recently, to investigate whether green tea consumption has an etiological association with PCa, a case-control study was conducted in Hangzhou, southeast China during 2001–2002^[144]. In this study, 130 incident patients with histologically confirmed adenocarcinoma of the prostate and 274 hospital inpatients without PCa or any other malignant diseases and matched to the age of cases were monitored. Information on duration, quantity and frequency of usual tea consumption, as well as the number of new batches brewed per day, were collected by face-to-face interview using a structured questionnaire. The risk of PCa for tea consumption was assessed using multivariate logistic regression adjusting for age, locality, education, income, body mass index, physical activity, alcohol consumption, tobacco smoking, total fat intake, marital status, age at marriage, number of children, history of vasectomy and family history of PCa. Among the cases, 55.4% were tea drinkers compared to 79.9% for the controls and almost all the tea consumed was green tea. The PCa risk was found to be declined with increasing frequency, duration and quantity of green tea consumption. The dose response relationships were also significant, suggesting that green tea imparts chemopreventive effects against PCa in humans^[144].

Clinical trials with green tea

A phase I trial of green tea extract in patients with solid tumors was conducted to ascertain the maximum tolerated dose, toxicity, and pharmacology of oral green tea extract. This study concluded that 1.0 g/m² of green tea extract three times a day [equivalent to 7 to 8 Japanese cups (120 mL) of green tea] is well tolerated and is not associated with any side effects^[145]. One recent phase II clinical trial explored the anti-neoplastic effects of green tea in patients with metastatic androgen-independent PCa^[146]. In this study, forty-eight patients were instructed to take 6 g of green tea per day orally in 6 divided doses. Results from this study showed that only one patient within this 42-patient cohort manifested a 50% decline in PSA values from baseline, but this reduction was not sustained beyond 2 months. Although green tea was tolerated well, a notable percentage of patients experienced adverse effects such as insomnia, fatigue etc., presumably from caffeine present in the tea. It should however, be noted that this study was conducted in patients with metastatic androgen-independent PCa and therefore, in principle, is not a representation of the chemopreventive effects of green tea. Furthermore, the median time on this study was only one month, whereas, prior pre-clinical data have been suggesting that green tea requires prolonged exposure to exert its antitumor activity^[110,112]. Taken into consideration the drawbacks of this trial, the negative findings of this study do not contradict the results of earlier epidemiological studies, which suggest that green tea may confer antitumor effects in a relatively healthy population. Thus, for an ideal prospective study, a population with high risk for PCa development should be considered and the length of exposure of green tea to the subjects should be taken into consideration.

Bettuzzi *et al*^[147] recently carried out a one-year proof-of-principle clinical trial to assess the safety and efficacy of GTCs for the chemoprevention of CaP in high-grade prostate intraepithelial neoplasia (HG-PIN) volunteers. Sixty volunteers with HG-PIN, were enrolled in this double-blind, placebo-controlled study. Daily treatment consisted of three GTCs capsules, 200 mg each (total 600 mg/d). After one year, only one tumor was diagnosed among the 30 GTC-treated men (incidence, approximately 3%), whereas nine cancers were found among the 30 placebo-treated men (incidence, 30%). Total prostate-specific antigen did not change significantly between the two arms, but GTCs-treated men showed values constantly lower with respect to placebo-treated ones. International Prostate Symptom Score and quality of life scores of GTC-treated men with coexistent

benign prostate hyperplasia (BPH) improved, reaching statistical significance in the case of the International Prostate Symptom Scores. No significant side effects or adverse effects were documented. This is the first study showing that GTCs are safe and very effective for treating premalignant lesions before PCa develops. As a secondary observation, administration of GTCs was also found to reduce lower urinary tract symptoms, suggesting that these compounds might also be of help for treating the symptoms of BPH. Confirmation of these findings in another group of patients is awaited.

Conclusion and future perspectives

Prostate cancer exists in either a latent, clinically insignificant form or in an aggressive form that progresses to various other body sites. Moreover, it is a complicated malignancy with tremendous heterogeneity of androgen-dependent and androgen-independent forms and because of the co-existence of multiple pathological entities, it has not been possible to provide satisfactory treatment options for this disease. Thus, chemoprevention with a naturally occurring non-toxic agent such as green tea could be useful in the management of this disease.

Recent pre-clinical studies have shown that tea and its constituents inhibit cell cycle, induce apoptosis and modulate multiple signaling pathways in a fashion that encourages the elimination of precancerous and cancerous cells. The uniqueness of the action of tea perhaps lies in its specificity of killing cancer cells without affecting the growth of normal cells. Although studies on tea polyphenols demonstrate its efficacy as a potent chemopreventive agent against PCa, there are still many gaps in our current awareness. There are certain factors such as bio-availability, tissue level of tea constituents, tea type, drinking habit, race, *etc.* that need to be taken care of before a recommendation could be made for tea polyphenols as preventive or therapeutic agent for human use. The bio-availability of the active polyphenolic constituents after tea consumption by laboratory animals and humans is poorly defined. Yang *et al* and others^[148–150] have measured the concentration of tea polyphenols in human plasma, saliva, feces and urine after consuming decaffeinated green tea and found that EGCG was in lesser concentration than EGC. Therefore, a great deal of laboratory research and many more epidemiological studies are needed for obtaining conclusive evidence. The increase or decrease of PSA and IGF-1 and IGFBP3 in relation to tea consumption and levels of tea polyphenols in urine samples may be used as biomarkers in PCa chemoprevention. This type of study could answer the question of how much tea should be con-

sumed by humans for PCa chemoprevention and explain the mechanism involved.

Prostate cancer is a disease of many etiological factors and involves several mechanisms in its progression. Therefore, the modulation of a single mechanism alone may not completely impede the progression of PCa. Therefore, a strategy of acting on multiple signaling pathways using a combination of chemopreventive agents should be explored for PCa chemoprevention in pre-clinical studies. For such a type of combination chemoprevention strategy, the agents should be selected based on their mechanism of action in such a way that two or more signaling pathways are attacked with two or more agents to impart a synergistic response against PCa. Because of the promising effects of tea consumption on tumor induction in animals and in a case control study, we recommend that this effect should be examined in a large population.
