Aim: To develop a population pharmacokinetic model for the immunosuppressant ciclosporin in Chinese children with aplastic anemia and to identify covariates influencing ciclosporin pharmacokinetics.

Methods: A total of 102 children with either acquired or congenital aplastic anemia aged 8.8 ± 3.6 years (range 0.9–17.6 years) were included. Therapeutic drug monitoring (TDM) data for ciclosporin were collected. The population pharmacokinetic model of ciclosporin was described using the nonlinear mixed-effects modeling (NONMEM) VI software. The final model was validated using bootstrap and normalized prediction distribution errors.

Results: A one-compartment model with first-order absorption and elimination was developed. The estimated CL/F was 15.1, which was lower than those of children receiving stem cell or kidney transplant reported in the West (16.9–29.3). The weight normalized CL/F was 0.45 (range: 0.27–0.70) $\text{L} \cdot \text{h}^{-1} \cdot \text{kg}^{-1}$. The covariate analysis identified body weight, serum creatinine and concomitant administration of the anabolic steroid stanozolol as individual factors influencing the CL/F of ciclosporin.

Conclusion: Our model could be used to optimize the ciclosporin dosing regimen in Chinese children with aplastic anemia.

Introduction

Aplastic anemia is defined as peripheral blood pancytopenia caused by bone marrow failure. Severe aplastic anemia is a life-threatening disorder with an overall mortality of 75%^[1]. The definitive therapy for severe aplastic anemia is hematopoietic stem cell transplantation. Ciclosporin in association with antithymocyte globulin and steroids is an alternative therapeutic option for patients for whom there are no human leukocyte antigen (HLA)-identical related stem cell donors^[2].

After absorption in the duodenum and the jejunum, ciclosporin binds primarily to lipoproteins and erythrocytes, is

widely distributed in the body, and is metabolized by CYP3A4 and CYP3A5 (mainly in the liver and, to a lesser extent, in the intestine and kidneys). The main route of elimination is via the biliary tract^[3]. Ciclosporin has a narrow therapeutic index and high inter-individual pharmacokinetic variability, making individualized therapy essential for treatment success. In current clinical practice, most centers use whole blood trough concentrations (C_0) to adjust the individual dose. The primary goal is to maintain C_0 within a predefined therapeutic range. Concentration-controlled dosage adaptation is often performed. However, despite widespread use of this strategy, it is still difficult to quickly determine a stable dose that will achieve the target C_0 because of numerous demographic, biological and clinical factors influencing ciclosporin pharmacokinetics, including weight, age, serum creatinine and concomitant medication^[4]. Therapeutic drug monitoring (TDM) is mandatory for pediatric patients, who exhibit wider pharma-

cokinetic variability than adults^[5].

Population pharmacokinetics, which integrates different effects of variables on drug exposure, has great potential for dosage individualization^[6]. The population pharmacokinetic approach has been used for determining the ciclosporin dose in children who have received a transplant^[7-9]. However, pharmacokinetic data for children with aplastic anemia are limited, and a population pharmacokinetic analysis of ciclosporin has not been conducted in this critical population. A thorough understanding of the developmental aspects (*ie*, the impact of age on ciclosporin clearance) and quantification of the influences of different clinical and biological covariates are required to individualize ciclosporin therapy.

The aims of our study were to develop a population pharmacokinetic model of ciclosporin, using a large TDM database, in children with aplastic anemia and to identify the covariates influencing ciclosporin pharmacokinetics.

Patients and methods

Patients

Children with either acquired or congenital aplastic anemia were considered for inclusion in this observational population pharmacokinetic study if at least one ciclosporin blood concentration was assayed for TDM. The study was undertaken in the Children's Hospital of Zhejiang University, Hangzhou, China.

Ciclosporin (gelatin capsule or liquid solution, NEOCYPIN, microemulsified formulation, Hangzhou, China) was given orally twice daily with an initial dose of 2.5 mg/kg. Dosage adjustment was based on TDM results to achieve a target C_0 of 200 ng/mL^[10]. The concentration of ciclosporin was determined after at least 10 days of consistent administration in order to reach the steady state.

The following data were collected: detailed dosing history, age, gender, body weight, type of disease, white blood cell count, absolute neutrophil count, hemoglobin level, platelet count, serum creatinine concentration and concomitant medications. Patients with incomplete information and patients who did not comply with treatment were excluded. This clinical trial was designed in accordance with legal requirements and the Declaration of Helsinki and was approved by the local ethics committee.

Assay of ciclosporin

Ciclosporin blood concentrations were determined by fluorescence polarization immunoassay technology FPIA (TDX/FLX; Abbott Laboratories, Abbott Park, IL, USA). The lower limit of quantification was 25 ng/mL, and the linearity ranged from 25 to 1500 ng/mL, with a coefficient variation of less than 4%.

Pharmacokinetic analysis

Pharmacokinetic analysis was carried out using the nonlinear mixed effects modeling program NONMEM VI (V2.0; Icon Development Solutions, USA). The first-order conditional estimation (FOCE) method with the interaction option was used to estimate pharmacokinetic parameters and associated

variability.

The one-compartment open model with first-order elimination was tested. Inter-individual variability of the pharmacokinetic parameters was estimated using an exponential model expressed as follows:

$$\theta_i = \theta \times \exp(\eta_i^\theta)$$

where θ is the typical population value of the pharmacokinetic parameter and η_i^θ is the difference between the log-transformed individual-specific parameter and the log-transformed parameter for the typical individual and represents the random effect for parameter θ in patient i . The η_i^θ values are independent, identically distributed random variables that are normally distributed around 0 with variance ω^2 , and i is the variable for the i th individual.

Residual variability (additive, proportional, exponential or mixed) models were selected according to improvement of the objective function value (OFV) and visual inspection of routine diagnostic plots, including observed (DV) *versus* individual prediction (IPRED), DV *versus* population prediction (PRED) and conditional weighted residuals (CWRES) *versus* PRED.

Covariate analysis

The relationship between body weight and pharmacokinetic parameters was modeled with the following equation:

$$P_i = P_{\text{std}} \times (WT_i / WT_{\text{std}})^{\text{PWR}}$$

where P_i is the pharmacokinetic parameter of the i th individual, WT_i is the body weight of the i th individual and P_{std} is the parameter of an individual with a body weight WT_{std} of 70 kg. The PWR is the allometric coefficient: 0.75 for the apparent clearance (CL/F) and 1 for the apparent volume of distribution (V/F)^[11, 12].

The additional effects of age, gender, white blood cell count, absolute neutrophil count, hemoglobin level, platelet count, serum creatinine concentration and concomitant medication (prednisone and stanozolol) were investigated as potential variables influencing pharmacokinetic parameters.

The selection of variables was determined using a forward and backward selection process. The OFV determined by NONMEM was used as a diagnostic criterion, with a ΔOFV of 3.84 points corresponding to a statistically significant difference between hierarchical models ($P=0.05$, χ^2 distribution with one degree of freedom). The contribution of each covariate was confirmed by a stepwise backward deletion ($\Delta\text{OFV}=6.64$, $P=0.01$, χ^2 distribution).

Model validation

The stability and performance of the final model were assessed by means of an internal validation method involving a nonparametric bootstrap with re-sampling and replacement. Re-sampling was repeated 500 times, and the values of the estimated parameters from the bootstrap procedure were compared with those estimated from the original data set. The entire procedure was performed in an automated fashion, using Perl-speaks-NONMEM (PsN)^[13].

Simulation-based diagnostics were performed by using normalized prediction distribution errors (NPDE)^[14]. The

dataset was simulated 500 times using the final population pharmacokinetic parameters (typical PK parameters, inter- and intra-individual variability and residual error). For NPDE, a cumulative distribution was assembled for each observation with the 500 simulated concentrations. The NPDE is expected to follow the $N(0,1)$ distribution^[15]. The following graphs were plotted using an NPDE R package (v1.2): (i) QQ-plot of the distribution of the NPDE versus the theoretical $N(0,1)$ distribution; (ii) histogram of the NPDE.

Predictive performance

The predictive performance of the developed model was evaluated using the following simulation scenario^[16]:

Ten percent of children ($n=10$) were randomly removed from the dataset. The parameters for the remaining children ($n=92$) were re-estimated. The new model was employed to predict the C_0 of the 10 children who were not used for the re-estimation of the parameters. An NPDE was assembled for each observation with the 500 simulated concentrations.

Results

One hundred and two children with aplastic anemia were recruited for this population pharmacokinetic study between 2003 and 2009. The mean $\pm$ SD age was 8.8 $\pm$ 3.6 years (range 0.9–17.6), and the mean $\pm$ SD body weight was 31.3 $\pm$ 12.7 kg (range 6.5–69.0). The children's characteristics are shown in

Table 1.

Population pharmacokinetic modeling

A total of 592 trough blood ciclosporin concentrations were available for population modeling (a mean of 6 samples per patient). The median (range) of TDM sampling time was 12.1 (10.0–16.0) h post-dose. Inter-individual variability was best described by an exponential model and was then estimated for the absorption rate constant (K_a) and apparent oral clearance (CL/F). The typical K_a value of 0.68 h⁻¹ was fixed according to the previously reported value^[6]. Adding a lag time did not improve the model's performance, as judged by the OFV and routine goodness-of-fit plots. Residual variability was best described by a combined proportional and additive model.

After incorporating body weight into the model structure using allometric scaling factors (0.75 for CL/F and 1 for V/F), the OFV significantly decreased, by 15.9. In forward selection processes, influence of body weight, serum creatinine, stanozolol, prednisone and absolute neutrophil count on the CL/F produced significant decreases in the OFV. In the backward selection process, only the significant covariates of weight, serum creatinine and stanozolol were retained (Table 2).

The weight-normalized apparent clearance (CL/F) was 0.45 (range: 0.27–0.70) L·h⁻¹·kg⁻¹. Figure 1 shows the relationship between age and body weight on the allometric weight-normalized CL/F. After incorporation of body weight with

Figure 1. Individual ciclosporin clearance (normalized to weight or allometric weight) plotted against age.

allometric scaling, there was no effect of age on the CL/F .

Routine diagnostic plots, including observed *versus* individual prediction, observed *versus* population prediction and conditional weighted residuals *versus* population prediction, indicate goodness of fit (Figure 2). The mean parameter estimates resulting from the bootstrap procedure very closely agreed with their respective values from the final population model, indicating that the estimates for the population pharmacokinetic parameters in the final model were accurate

and that the model was stable. The results of 500 bootstrap replicates are summarized in Table 3. The NPDE is presented in Figure 3. The Shapiro-Wilk test of normality was significant, but significance is often observed when analyzing a large number of observations^[17]. Apart from a few outliers, the NPDE plots did not pinpoint a particular deficiency in the model. The good predictive performance of the developed model in predicting C_0 is shown in the simulation scenario described above. The mean and variance of the NPDE were -0.19 (Wilcoxon signed rank test, $P=0.08$) and 1.05 (Fisher variance test, $P=0.75$), respectively. The NPDE is normally distributed (Shapiro-Wilk test, $P=0.22$) and is presented in Figure 4. The individual predicted concentrations are significantly correlated with observed concentrations, with a correlation coefficient of 0.796 ($P<0.01$, Pearson test). The difference is not significant between the two groups ($P=0.627$, paired t test).

Discussion

This first population pharmacokinetic study of ciclosporin in children with aplastic anemia was undertaken to describe the pharmacokinetics of ciclosporin in this special population and to evaluate the influence of developmental, biological and clinical factors affecting drug exposure. Our results showed that a one-compartment model with first-order absorption and elimination was adequate for data modeling and that body weight, serum creatinine concentration and stanozolol administration had significant impacts on CL/F .

The estimated CL/F in children with aplastic anemia was comparable with that reported in children before renal transplantation but seems to be lower than that reported in children after stem cell or renal transplantation (Table 3).

In accord with the principles of allometry and the approach adopted by Fanta *et al* in studying pediatric renal transplant recipients^[7], we developed an allometry-based population pharmacokinetic model for ciclosporin: body weight was incorporated with allometric coefficients of 0.75 for CL/F and 1 for V/F^[11]. The allometric approach was confirmed by estimating the CL/F of a patient with a 70 kg standard body weight: the estimated CL/F of 31.5 L/h was in agreement with the published CL/F values for adults^[18, 19]. After incorporating

body weight into the model, age did not significantly influence the CL/F, which was in agreement with previous results in pediatric renal (pre-) transplant patients^[7, 8].

The effect of renal function on ciclosporin CL/F is controversial. No significant effect was revealed in children after renal and stem cell transplantation^[8, 9]. In contrast, Fanta *et al* reported a significant effect of serum creatinine on CL/F in renal pre-transplant children^[7]. It has been demonstrated

that renal dysfunction decreases hepatic drug-metabolism enzyme activities, including CYP3A4, in patients with kidney disease^[20, 21]. The correlation between renal function and CYP3A4 activity remains to be confirmed in patients undergoing ciclosporin therapy.

Children undergoing immunosuppressive therapy often take steroids^[22, 23]. *In vitro* studies have shown that steroids are substrates, inducers and inhibitors of CYP3A. Steroids reduce the CYP450 3A metabolism of ciclosporin via competitive inhibition^[24]. Numerous *in vivo* studies have examined the effects of steroids (methylprednisolone, prednisolone, or prednisone) on ciclosporin concentrations in adult patients; however, controversial results have been reported^[25]. In the present study, 6 different steroids (prednisone, stanozolol, triamcinolone, testosterone undecanoate, methylprednisolone and dexamethasone) were co-administered with ciclosporin, but only prednisone and stanozolol were tested in the model, as there were sufficient samples to test them. Prednisone and stanozolol showed significant effects in the forward covariate selection process, while only stanozolol was retained after backward selection, indicating that stanozolol significantly inhibited CYP3A4-mediated ciclosporin metabolism in children. Careful monitoring of ciclosporin concentrations and dosage adjustment based on TDM results is mandatory when ciclosporin and stanozolol are coadministered.

Our study has some limitations. We planned to prospectively collect a large ciclosporin TDM dataset in children with aplastic anemia. When the recruitment began in 2003, some covariates (eg, cholesterol levels, hematocrit, CYP3A4, and ABCB1 genotype) were not routinely collected, so their impact could not be tested^[26]. In clinical practice, only C_0 is routinely measured to adjust the dose of ciclosporin in children with aplastic anemia, and it was thus used in this population pharmacokinetic analysis. In transplanted children, concentrations measured at 2 h post-dose (C_2) are better correlated with the AUC^[5], which is considered to be the best marker of drug exposure to predict the drug's therapeutic effect. Given the important difference in pharmacokinetic parameters between two populations, a prospective study is warranted to evaluate the potential benefits of C_2 - and/or AUC-based dosing individualization of ciclosporin in children with aplastic anemia.

In conclusion, a population pharmacokinetic model of ciclosporin was developed in Chinese children with aplastic anemia. Weight, serum creatinine and stanozolol administration significantly influenced the ciclosporin CL/F. The model developed here will aid in optimizing ciclosporin doses in children.
