Background: Conflicting results have been reported regarding the predicative roles of alloreactive natural killer (NK) cells on the outcomes of transplantation in leukaemia patients.

Methods: We prospectively analysed the human leukocyte antigen (HLA) typing of donor–recipient pairs and the KIR typing of the donors in 97 CML patients to address the predictive roles of NK cells in relapse undergoing T-cell-replete haploidentical transplantation.

Results: Patients with class I ligands for the donor-inhibitory KIR gene exhibited decreased molecular and haematologic relapse rates ($P=0.003$ and $P=0.015$, respectively). There was a significantly reduced risk of molecular and haematologic relapse in patients with HLA-C1C2 or C2C2 who accepted donors with KIR2DS1 or in patients with HLA-Bw4 who accepted donors with KIR3DS1 ('recipient with relevant KIR ligand for donor-activating KIR', $n=25$), compared with the remaining transplants ($n=72$, $P=0.009$ and $P=0.009$, respectively). In addition, the presence of class I ligand in the recipients of donor-activating KIR contributed to a decreased relapse rate in patients lacking class I ligand in the recipient of donor-inhibitory KIR ($P=0.04$ and $P=0.03$, respectively).

Conclusions: This study suggests that the presence of class I ligands for the donor-activating or donor-inhibitory KIR gene in the recipient might confer some protection against leukaemic relapse in T-cell-replete haploidentical transplantation.

Natural killer (NK) cells are lymphocytes that are critical for innate immunity against malignant or virally infected cells. In recipients, the functions of NK cells are primarily modulated by the expression of activating and inhibitory receptors, as well as their relevant ligands (Raulet and Vance, 2006). The alloreactivity of NK cells depends on the expression of a KIR and its MHC-I ligand in the donor (for education) and on the absence of the MHC-I ligand in the recipient (for relief from inhibition). In biological studies of NK cells, two general models that define NK alloreactivity have arisen: a mismatch between the donor and recipient killer immunoglobulin receptor (KIR) ligands (ligand-ligand model); or

recipients lacking KIR ligands for donor-inhibitory KIR receptors (missing self-model) (Ruggeri *et al*, 2002; Kim *et al*, 2005). Furthermore, in alloreactive NK-cell responses, KIR2DS1 expression offers a remarkable advantage because it allows for the efficient killing of C2/C2 or C1/C2 myelomonocytic dendritic cells (DCs) and T-cell blasts (Sivori *et al*, 2011). The interaction between KIR3DS1 and human leukocyte antigen (HLA)-Bw4 was predictive of progression-free survival after autologous stem cell transplantation (SCT) in patients with multiple myeloma (Gabriel *et al*, 2010). Thus, KIR2DS1 and KIR3DS1 expression in HSC donors could substantially increase the size of the alloreactive NK-cell subset.

Family HLA-mismatched/haploidentical haematopoietic SCT is a feasible therapeutic approach for patients with lethal malignant haematological diseases who lack an HLA-matched donor. Several haploidentical transplant protocols have been established worldwide (Huang, 2008; Fuchs *et al*, 2010). Human leukocyte antigen mismatches can trigger donor *vs* recipient NK-cell alloreactivity (Ruggeri *et al*, 1999, 2007; Leung *et al*, 2004, 2005; Zhao *et al*, 2011). However, conflicting results have been reported regarding the impact of the ligand-ligand model or the missing self-model on the outcomes of transplantation in leukaemic patients (Zhao *et al*, 2011). More interestingly, in the setting of T-cell-replete haploidentical HSCT, we observed that a KIR ligand mismatch was a strong risk factor for a high incidence of relapse and decreased overall survival (OS), in direct contrast to the findings of Perugia's group regarding T-cell depletion (Huang *et al*, 2007). Moreover, in another limited series of T-cell-replete haploidentical transplants, recipients lacking KIR ligands for donor-inhibitory KIR receptors showed a tendency towards a higher relapse rate (Zhao *et al*, 2007). Although these prior results have been inconsistent or even contradictory, the reasons for this discordancy are currently unclear, but they might reflect differences in patient heterogeneity, the involvement of donor-activated KIR genes and post-transplantation alloreactive NK-cell reconstitution.

CML is considered to be one of the leukaemias most susceptible to immune manipulation (Simula *et al*, 2007). Yong *et al* (2009) demonstrated that *in vitro*, primitive, quiescent CD34+ cells in CML were targeted by expanded NK cells. Kijima *et al* (2011) demonstrated that missing self-recognition mediated by NK cells protected mice from primary CML *in vivo*, suggesting that NK-cell recognition had the potential to cure CML. Our previous report showed that HLA-mismatched/haploidentical HSCT was a feasible therapeutic option for CML patients without an HLA-matched sibling (Xiao-jun *et al*, 2008; Jiang *et al*, 2011). Considering that the conflicting roles of NK cells in protection against leukaemia, inferred from retrospective haploidentical transplantation analysis, might have been caused by patient heterogeneity, we prospectively analysed the HLA typing of donor-recipient pairs and the KIR typing of the donor in relatively purified samples from patients with CML, to address further the predictive roles of NK cells in the relapses of patients undergoing T-cell-replete haploidentical transplantation. These transplants are particularly important to investigate, because they allow for the evaluation of the influence of inhibitory and activating donor KIR types in the presence in recipients of the relevant KIR ligands on clinical outcomes without the confounding effects of disease heterogeneity. The findings could lead to better donor selection between donors and recipients.

PATIENTS AND METHODS

Patients. We enrolled patients with CML who were suitable for allo-HSCT and who had no related or unrelated HLA-identical donors. In total, 134 patients with CML underwent T-cell-replete HLA-haploidentical transplantation between August 2003 and December 2009 at the Peking University Institute of Hematology. Written informed consent was obtained from all of the patients and donors before their entry into the study, in accordance with the Declaration of Helsinki. In this cohort, 37 patient-donor pairs refused to undergo KIR and HLA-C genotyping. Therefore, the remaining 97 consecutive CML patients were enrolled in the study. Both the patients and their donors provided written informed consent, and the Institutional Review Board of the Peking University Institute of Hematology approved this study. The characteristics of the 97 patients are presented in Table 1.

Conditioning regimen, mobilisation and collection of stem cells, and GVHD prophylaxis. All of the patients received

myeloablative regimens, including a combination of cytosine arabinoside (Ara-C) ($4 \text{ g m}^{-2} \times 2$ days, on days -10 and -9), busulfan (12 mg kg^{-1} administered in 12 doses over 3 days, on days -8 , -7 and -6), cyclophosphamide ($1.8 \text{ g m}^{-2} \times 2$ days, on days -5 and -4), Simustine (MeCCNU) (250 mg kg^{-1} on day -3), and rabbit anti-human thymocyte immunoglobulin (thymoglobulin 2.5 mg kg^{-1} per day i.v. of the Sangstat product) on days -5 through -2 .

The donors received rhG-CSF (Filgrastim) $5 \mu\text{g kg}^{-1}$ daily for 5–6 days. On the fourth day, bone marrow (BM) cells were harvested. The target total nucleated cell count was 3.0×10^8 (median, 3.77×10^8 , range, $0.24\text{--}8.16 \times 10^8$) cells per kg of recipient weight. On the fifth and sixth days, peripheral blood progenitor cells (PBPCs) were collected. The target mononuclear cell count was 3.0×10^8 (median, 3.58×10^8 , range, $0.91\text{--}11.7 \times 10^8$) cells per kg of recipient weight. The fresh and unmanipulated BM and PBPCs were infused into the recipients on the day of collection.

The prophylaxis for GVHD included cyclosporine A (CsA) and short-term methotrexate (MTX) with mycophenolate mofetil (MMF) treatment. Cyclosporine A was started intravenously on day -9 at a dose of 2.5 mg kg^{-1} and was switched to the oral formulation as soon as the patient was able to tolerate oral medication after engraftment. The dosage was adjusted to the patients' blood levels. Mycophenolate mofetil was administered orally at a dose of 0.5 g every 12 h, from day -9 before transplantation to day 30 after transplantation and then 0.25 g every 12 h for 1–2 months. The dosage of MTX was 15 mg m^{-2} , and it was administered i.v. on day 1, while the dose was 10 mg m^{-2} on days 3, 6 and 11 after transplantation. The diagnosis and grading of GVHD were established according to published criteria. In all of the recipients, rhG-CSF was administered subcutaneously at a dose of $5 \mu\text{g kg}^{-1}$ per day from day 6 after transplantation until the neutrophil count reached 0.5×10^9 cells per litre for 3 consecutive days (Xiao-jun *et al*, 2008; Jiang *et al*, 2011).

Outcome definition. The haematologic response criteria were defined as follows. Complete haematologic remission (CHR) was defined as a myeloblast count of $\leq 5\%$ in the BM, no myeloblasts in the peripheral blood, neutrophil and platelet counts of at least 1.5×10^9 per litre and 100×10^9 per litre, respectively, and no evidence of extramedullary involvement. Complete molecular remission (CMR) was defined as an undetectable BCR-ABL transcript level. Post-transplantation molecular relapse was defined as positive BCR-ABL transcripts confirmed in two consecutive assays after previously achieving CMR or a persistent BCR-ABL transcript increase of more than 1 log. Cytogenetic relapse was defined as Philadelphia (Ph) chromosome reappearance, and haematologic relapse was defined according to the criteria of the World Health Organization (WHO). Event-free survival was defined as the time that elapsed between allo-HSCT and the appearance of one of the following events: the absence of haematologic response at 3 months; the loss of previously obtained CHR, MCR or CCR; post-transplantation molecular relapse; relapse in AP or BP; or death from any cause. Overall survival was defined as the time from the beginning of allo-HSCT to death from any cause (Xiao-jun *et al*, 2008; Jiang *et al*, 2011).

Minimal residual disease monitoring. Minimal residual disease (MRD) was evaluated in recipient BM cells on days 30, 60, 90, 120, 150 and 180 and then every 1 year after HSCT. Cytogenetic analysis was performed by fluorescence *in situ* hybridisation (FISH). BCR-ABL transcripts were detected by analysing BM with nested reverse transcriptase PCR before 2004 and with quantitative real-time PCR after 2004. The normalisation ratios of BCR-ABL transcript levels in quantitative PCR analysis were obtained through comparison with the levels of ABL transcript, as

Table 1. Patients' characteristics

Factor	Total (n = 97)	Expressing a class I ligand in the recipient for donor-inhibitory KIR (n = 23)	Lacking a class I ligand in the recipient for donor-inhibitory KIR (n = 74)	P-value
Median age at transplantation, years old (range)	28 (7–57)	33 (15–54)	26 (7–57)	0.081

Presence of HLA-C2 in recipients of donor-KIR2DS1	15 (16%)	9 (39%)	6 (8%)	<0.01
Presence of HLA-Bw4 in recipients of donor-KIR3DS1	19 (20%)	10 (44%)	9 (12%)	<0.01
Presence of HLA-C2 or HLA-BW4 in recipients of donor-KIR2DS1 or -KIR3DS1	25 (26%)	11 (48%)	14 (19%)	0.01
Accepted TKI therapy post-transplantation	15 (15%)	0 (0%)	15 (20%)	0.019
Accepted DLI therapy post-transplantation	14 (14%)	0 (0%)	14 (19%)	0.036

Abbreviations: AP = accelerated phase; BC = blast crisis; CP1 = chronic phase 1; CP2 = chronic phase 2; DLI = donor lymphocyte infusion; F/F = female/female; F/M = female/male; HLA = histocompatibility; M/F = male/female; M/M = male/male; PLT = platelet; TKI = tyrosine kinase inhibitor; TNC = total nuclear cell; WBC = white blood cell.

previously reported (Xiao-jun *et al*, 2008; Jiang *et al*, 2011). The sensitivity of the Bcr-Abl assay for detecting MRD was 0.001%.

Imatinib and donor lymphocyte infusion. Donor lymphocyte infusion (DLI) and imatinib mesylate were given to patients who had a molecular, cytogenetic or haematologic relapse after HSCT, following a trial of immunosuppressant withdrawal. In patients without GVHD, G-CSF-mobilised peripheral blood stem cell grafts were used for DLI. Otherwise, imatinib mesylate was given. The initial dose of imatinib mesylate was 400 mg per day, and it was adjusted, when necessary, according to response and tolerance (Xiao-jun *et al*, 2008; Jiang *et al*, 2011).

HLA and KIR genotyping. Patient and donor DNA was prepared from peripheral blood mononuclear cells and was used for HLA typing and KIR genotyping before transplantation. The samples were stored at -40°C . Serological and molecular HLA typing were performed as described by Lu *et al*. Recipient HLA-C and HLA-B alleles were identified by high-resolution DNA-based HLA typing and were segregated, where appropriate, into the epitope groups HLA-C group 1 (HLA-C^{Asn80}: HLA-Cw1, 3, 7, 8, 13, 14 alleles), HLA-C group 2 (HLA-C^{Lys80}: HLA-Cw2, 4, 5, 6, 12, 15, 17, 18 alleles), and HLA-Bw4.

The KIR genotyping was performed on genomic DNA from haploidentical donors of haematopoietic stem cells, using PCR amplification with sequence-specific primers, as described previously, or using a KIR genotyping kit (One Lambda, Canoga Park, CA, USA), according to the manufacturer's instructions (Huang *et al*, 2007; Zhao *et al*, 2007).

Definitions of two models of NK-cell alloreaction. The following KIR receptors and their ligands were considered: KIR2DL1 with HLA-C 'group 2'-related alleles, KIR2DL2/3 with HLA-C 'group 1'-related alleles, and KIR3DL1 with the HLA-Bw4 allele. The *ligand-ligand model* was defined as follows: patients were separated into two groups according to the HLA typing of the donors and patients, specifically those with or without a KIR ligand mismatch (the absence of one donor KIR ligand in the recipient) (Ruggeri *et al*, 2007). The *missing self model* was defined as follows: the missing-ligand model included all of the donor-recipient pairs in which there was a mismatch between at least one KIR inhibitory gene in the donor and the HLA molecule(s) in the recipient (Leung *et al*, 2004, 2005).

Statistical analysis. The associations between patient characteristics or pre-transplantation variables and post-transplantation

outcomes were analysed using the Kaplan–Meier method, or they were calculated using cumulative incidence curves to accommodate competing risks. R software (R Development Core Team (2006). R: A Language and Environment for Statistical Computing. R Foundation for Statistical Computing, Vienna, Austria. ISBN 3-900051-07-0, URL: <http://www.R-project.org>.) was used to calculate the cumulative incidence, considering the presence of competing risk. Event-free survival and OS were estimated using Kaplan–Meier methods, and the probabilities of relapse, transplant-related mortality (TRM), grade II to IV aGVHD, and both absolute neutrophil count (ANC) and platelet count (PLT) recovery were calculated as cumulative incidences to adjust the analysis for competing risks. To evaluate the independent effects of missing ligand transplants and KIR ligand-mismatched transplants, Cox regression analysis was performed. Factors included in the models were recipient and donor age, sex, sex mismatch, diagnosis (myeloid leukaemia vs lymphoid leukaemia), number of HLA-mismatched alleles, missing self transplants, KIR ligand-mismatched transplants, pre-transplantation risk category (AP + BC + CP2 vs CP1), and recipients with the relevant KIR ligand for donor-activated KIR. The final multivariate models were constructed using a forward stepwise model selection approach. The patient characteristics among the three groups were compared using chi-square statistics for categorical variables and with the Mann–Whitney *U* test for continuous variables. $P < 0.05$ was considered as statistically significant.

RESULTS

Patient characteristics. The patients' characteristics are provided in Table 1. In total, 96 of the 97 patients achieved WBC engraftment, and 92 of the 97 patients achieved PLT engraftment. One patient died on day 24 without WBC or PLT engraftment. All of the engrafted patients achieved complete donor chimaerism after transplantation. Sixty-five patients survived without leukaemia. Sixteen patients died of transplant-related complications after HSCT. Twenty-two patients had molecular relapse, of whom six accepted TKI therapy and returned to MMR, while the remaining sixteen patients progressed to haematological relapse. Eight of the sixteen relapsing patients died. In all, 2 patients did not complete the study, and 14 of 16 patients received DLI combined with TKI or chemotherapy. Of these 14 patients, 2 returned to MMR, and 6 patients are currently living with leukaemia. The median follow-up duration for the cohort was 6.7 years (range, 3.6–9.3 years). Of the 97 patients, there were 61 and 36 patients who had 0–I aGVHD and II–IV aGVHD, respectively. Among the 92 patients evaluated for the cGVHD who survived longer than 100 days, 58 patients had limited (31 patients) or extensive (27 patients) cGVHD.

The frequencies of inhibitory and activating KIR genes in this Chinese population were consistent with the gene frequencies reported in previously published studies. Specifically, the frequencies were 98% for KIR2DL1, 28% for KIR2DL2, 100% for KIR2DL3, 100%, 93% for KIR3DL1, 32% for KIR2DS1, 11% for KIR2DS2, 15% for KIR2DS3, 29% for KIR2DS5, 32% for KIR3DS1, and 55% for KIR haplotype BX.

Presence of a class I ligand in the recipient for donor-inhibitory KIR contributed to a decreased relapse rate. The data obtained as of 1 August 2013 were analysed, and the univariate effects of the demographic data on post-transplantation outcomes were analysed by the Kaplan–Meier method or were calculated using cumulative incidence curves to accommodate for competing risks.

There were 74 donor–recipient pairs lacking a class I ligand in the recipient for donor-inhibitory KIR and 23 present a class I ligand in the recipient for donor-inhibitory KIR. As shown in Figure 1, univariate analysis demonstrated that there were significantly increased molecular and haematologic relapse rates in patients lacking a class I ligand in the recipient for donor-inhibitory KIR (group A, $n = 74$), compared with those expressing a class I ligand in the recipient for donor-inhibitory KIR (group B, $n = 23$, $P = 0.003$ and $P = 0.015$, respectively, Figure 1A and B). Therefore, patients lacking a class I ligand in the recipient for donor-inhibitory KIR had longer EFS ($P = 0.024$, Figure 1C). There were similar incidences of aGVHD, cGVHD and TRM in patients lacking the KIR ligand for donor-inhibitory KIR, compared with those among patients expressing the KIR ligand for donor-inhibitory KIR. The OS in patients expressing the KIR ligand for donor-inhibitory KIR tended to be longer than that of patients lacking the KIR ligand for donor-inhibitory KIR, although these differences were not significant ($P = 0.137$).

No significant influences of a KIR ligand mismatch between the donor and the recipient on clinical outcomes, including relapse ($P = 0.722$), aGVHD ($P = 0.916$), cGVHD ($P = 0.838$), TRM ($P = 0.727$), OS ($P = 0.816$) and EFS ($P = 0.656$), were found in CML patients.

Presence of a class I ligand in the recipient for donor-activating KIR contributed to a decreased relapse rate. The activating donor KIR genes, including KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS5, and KIR3DS1, were found to have no significant influences on relapse. KIR2DS1 expression represents a remarkable advantage because it allows for the efficient killing of C2/C2 or C1/C2 myelomonocytic DCs and T-cell blasts. In addition, in patients with multiple myeloma, the interaction between KIR3DS1 and HLA-Bw4 predicts progression-free survival after autologous SCT. We hypothesised that this association would be observed only in donors with KIR2DS1 or KIR3DS1 and recipients with HLA-C1C2 or -C2/C2 or Bw4 because of the presence of a relevant KIR ligand for the activating KIR gene. We found a significantly reduced risk of molecular relapse among CML patients with HLA-C1C2 or -C2/C2

Figure 1. The effects of missing self between donors and recipients on clinical outcomes. The cumulative incidence estimates for the probability of molecular (A) and haematologic (B) relapse, as well as the Kaplan–Meier estimate for event-free survival (EFS, C) for CML patients lacking or expressing of the relevant KIR ligand (HLA-BW4 or HLA-C2 positive) for the donor-inhibitory KIR gene (group A, $n = 74$ or group B, $n = 23$) after haploidentical T-cell-replete transplantation.

whose donors were positive for KIR2DS1, compared with patients with HLA-C1C1 whose donors were positive for KIR2DS1 ($P=0.008$) or negative for KIR2DS1 ($P=0.024$, Figure 2A). Furthermore, the haematologic relapse rate among CML patients with HLA-C1C2 or -C2/C2 whose donors were positive for KIR2DS1 was significantly lower than that of patients with HLA-C1C1 whose donors were positive for KIR2DS1 ($P=0.010$, Figure 2B).

Similar to the predictive roles of donor KIR2DS1 and recipient HLA-C ligand, patients with HLA-Bw4-accepting donors with KIR3DS1 positivity tended to have lower molecular and haematologic relapse rates, compared with patients with HLA-Bw4-accepting donors with KIR3DS1 negativity ($P=0.058$ and $P=0.081$, respectively, Figure 3A and B). At the same time, molecular relapse in patients with HLA-Bw4-positive-accepting donors with KIR3DS1 positivity was significantly less common than in patients who were HLA-Bw4 negative ($P=0.048$, Figure 3A).

No effects of the recipients' HLA-Bw4 positivity or negativity on relapse were found. However, patients with HLA-C1C2 or -C2C2 ($n=59$) had lower molecular relapse rate ($10.53 \pm 5.06\%$ vs $34.72 \pm 8.01\%$, $P=0.026$) and haematologic relapse rates ($8.08 \pm 4.55\%$ vs $20.39 \pm 5.31\%$, $P=0.066$), compared with those of patients with HLA-C1C1 ($n=38$).

Next, we combined the above predictive model, specifically subgrouping patients with HLA-C1C2- or C2C2-accepting donors with KIR2DS1-positive patients or patients with HLA-Bw4-accepting donors with KIR3DS1 positive ('recipient with relevant KIR ligand for donor-activating KIR', $n=25$) and 'other' (the remaining transplants, $n=72$). The molecular relapse and haematologic relapse rates in patients in the 'recipient with

relevant KIR ligand for donor-activating KIR' group were significantly lower than those of the patients in the 'other' group ($P=0.009$ and $P=0.009$, Figure 4A and B). The donor-activated KIR gene with the relevant KIR ligand in recipients, including aGVHD, cGVHD, TRM, OS and EFS, was found to have no significant influences on the clinical outcomes of CML patients.

Presence of class I ligand in the recipient for donor-activated KIR contributed to a decreased relapse rate in recipient lacking a class I ligand for donor-inhibitory KIR. Because patients lacking a class I ligand for donor-inhibitory KIR had higher relapse rates than those expressing a class I ligand for donor-inhibitory KIR, we examined whether activating donor KIR2DS1 positivity or KIR3DS1 positivity with relevant HLA ligand in recipients could overcome the higher relapse rate in patients with a missing self between the donor and the recipient. Among the 74 patients without the KIR ligand for the donor-inhibitory KIR gene, there were 13 patients in the 'recipient with relevant KIR ligand for donor-activating KIR' group and 61 patients in the 'other' group. The molecular relapse and haematologic relapse rates in patients in the 'recipient with relevant KIR ligand for donor-activating KIR' group were significantly higher than those of the patients in the 'other' group ($P=0.04$ and $P=0.03$, Figure 5) among the patients with a missing self between the donor and the recipient.

There were no significant differences in recipient age, diagnosis, pre-transplantation risk category, HLA incompatibility, or doses of CD3+ T cells and CD34+ cells among the patients with or without a missing self between the donor and the recipient (Table 2). However, there were more patients with the relevant KIR ligand for a donor-activated KIR gene in the 'recipient expressing a class I ligand for donor-inhibitory KIR' group, compared with

Figure 2. The effects of donor KIR2DS1 positivity on the relapse of recipients with HLA-C2 ligand. The cumulative incidence estimate for the probability of molecular (A) and haematologic (B) relapse in CML patients who were HLA-C2 positive (HLA-C1C2 or HLA-C2C2) accepting donors with KIR2DS1 positivity, compared with those patients who were HLA-C2 negative (HLA-C1C1) accepting donors with KIR2DS1 positivity or negativity after haploidentical T-cell-replete transplantation.

Figure 3. The effect of donor KIR3DS1 positivity on the relapse of recipients with HLA-Bw4 ligand. The cumulative incidence estimate for the probability of molecular (A) and haematological (B) relapse in CML patients with HLA-Bw4 positive (HLA-BW4Bw4 or HLA-BW4BW6) accepting donors with KIR3DS1 positivity, compared with those patients with HLA-Bw4 positive (HLA-BW4Bw4 or HLA-BW4BW6) accepting donors with KIR3DS1 positivity or those patients who were HLA-Bw4 negative (HLA-BW6Bw6) after haploidentical T-cell-replete transplantation.

Figure 4. The effects of donor-activating KIR gene on the relapse of recipients with the relevant KIR ligand. The cumulative incidence estimate for the probability of molecular (A) and haematologic (B) relapse in CML patients with the relevant KIR ligand (HLA-BW4 or HLA-C2 positive) for donor-activating KIR gene (KIR2DS1 or KIR3DS1) after haploidentical T-cell-replete transplantation.

Figure 5. The effects of donor-activating KIR gene on the relapse of recipients with the relevant KIR ligand for the activating KIR gene but not for the inhibitory KIR gene. The cumulative incidence estimate for the probability of molecular (A) and haematologic (B) relapse in CML patients with the relevant KIR ligand (HLA-BW4 or HLA-C2 positive) for the donor-activating KIR gene (KIR2DS1 or KIR3DS1) but not for the donor-inhibitory KIR gene (with missing self between donor and patient) after haploidentical T-cell-replete transplantation.

those in the 'recipient lacking a class I ligand for donor-inhibitory KIR' group (Table 2).

Multivariate analysis confirmed that 7-year molecular relapse was best prevented by the combination of recipients having a relevant KIR ligand (HLA-C2 positive or HLA-Bw4 positive) for accepting donors with activating KIR gene positivity (KIR2DS1 or KIR3DS1) (HR 0.141 (0.019–1.047)), $P = 0.056$, Table 2). The absence of the KIR ligand for the donor-inhibitory KIR gene was also an independent risk factor for lower EFS (HR 3.102 (0.937–10.266), $P = 0.064$, Table 2). Additionally, multivariate analysis also demonstrated that high-risk CML (CP2 + AP + BC) was an independent predictor of OS, EFS and relapse. Transplant-related mortality was encouraged by donor KIR2DS3 positivity (HR 4.290 (1.544–11.921), $P = 0.005$) and was prevented by donor KIR2DS5 positivity (HR 0.121 (0.016–0.918), $P = 0.041$). Therefore, donor KIR2DS3 and donor KIR2DS5 played contrasting roles in predicting OS and EFS post-transplantation (Table 2). At the same time, having a donor with the KIR BX haplotype was an independent risk factor for 3–4 aGVHD post-transplantation (HR 4.096 (1.175–14.275), $P = 0.010$).

DISCUSSION

In the current study, we investigated the predictive roles of distinct models for NK-cell alloreactivity on haploidentical transplantation outcomes in patients with CML. By limiting the transplant setting of our study to patients with Bcr-Abl-positive CML who received T-cell-replete haploidentical transplant, we avoided procedural heterogeneities, such as variabilities in the conditioning regimens or the GVHD prophylaxis used, as well as the disease

heterogeneities, as observed in many other studies. To our surprise, although we avoided the impact of heterogeneous disease, we nevertheless demonstrated that, in this setting of T-cell-replete haploidentical HCT, CML patients lacking the ligand for their donors' inhibitory KIR tended to have increased relapse and inferior survival. Specifically, both the molecular and haematologic relapse rates were increased in recipient lacking a class I ligand for donor-inhibitory KIR. Therefore, the impact of therapeutic factors, such as DLI and TKI therapy for molecular relapse, was excluded. Furthermore, the patients' pre-transplantation CML risk levels were equal between the groups, and there were more patients receiving DLI or TKI therapy post-transplantation in the group of recipient lacking a class I ligand for donor-inhibitory KIR. However, this difference did not change the high relapse rate and inferior EFS in this group. Thus, the impact of disease heterogeneity on the conflicting effects of a missing self model was excluded. We found that a missing self model between donors and recipients was indeed associated with a high relapse rate in the setting of T-cell-replete transplantation, in agreement with our previous retrospective report (Huang *et al*, 2007; Zhao *et al*, 2007) and contrary to the findings reported in the setting of a potent T-cell-depleted haploidentical HSCT (Leung *et al*, 2004, 2005). Fuchs and colleagues also failed to find any significant differences in any patient outcomes when utilising the other proposed models, including ligand incompatibility, missing ligands, and gene–gene for stimulatory KIR, in the setting of non-myeloablative haploidentical HSCT study, utilising T-cell-replete grafts and a novel post-transplantation immunosuppressive regimen, including Cy (Symons *et al*, 2010). Furthermore, even in the setting of T-cell-depleted haploidentical transplantation, Ruggeri *et al* (2007) did not find any beneficial effects of a missing self model on clinical

Table 2. Multivariate analysis: factors affecting transplantation outcomes

Outcome and factors	OR (95% CI)	P-value
EFS		
CP2 + AP + BC vs CP1	3.064 (1.428–6.575)	0.004
Lacking vs expressing a class I ligand in the recipient for donor-inhibitory KIR	3.102 (0.937–10.266)	0.064
Donor KIR2DS3 (positive vs negative)	2.762 (1.216–6.275)	0.015
Donor KIR2DS5 (positive vs negative)	0.314 (0.109–0.901)	0.031
OS		
CP2 + AP + BC vs CP1	2.268 (0.993–5.183)	0.052
Donor KIR2DS3 (positive vs negative)	3.415 (1.402–8.319)	0.007
Donor KIR2DS5 (positive vs negative)	0.181 (0.043–0.774)	0.021
Molecular relapse		
CP2 + AP + BC vs CP1	4.109 (1.511–11.176)	0.006
Donor KIR2DS1(+) and recipient HLA-C2(+) or donor KIR3DS1(+) and recipients HLA-BW4(+) vs the remaining transplants	0.141 (0.019–1.047)	0.056
TRM		
Donor KIR2DS3 (positive vs negative)	4.290 (1.544–11.921)	0.005
Donor KIR2DS5 (positive vs negative)	0.121 (0.016–0.918)	0.041
3-4aGVHD		
KIR haplotype BX vs KIR AA	4.096 (1.175–14.275)	0.010
Abbreviations: aGVHD = acute graft-vs-host disease; AP = accelerated phase; BC = blast crisis; CP1 = chronic phase 1; CP2 = chronic phase 2; EFS = event-free survival; KIR = killer immunoglobulin receptor; OS = overall survival; TRM = transplantation-related mortality.		

outcomes. The reasons for these apparently discordant results are currently unclear. Further laboratory studies, such as NK-cell functional reconstitution differences between patients with and without a KIR ligand for donor-inhibitory KIR, would be more important (Vago *et al*, 2008; Triplett *et al*, 2009; Pfeiffer *et al*, 2010).

Interestingly, the preventative effects on relapse of activated donor KIR genes with the relevant HLA ligand in the recipients were found in the same group. At the same time, the higher relapse rate in recipient lacking a class I ligand for donor-inhibitory KIR was overcome by accepting donors with an activating KIR gene, including KIR2DS1 and KIR3DS1, if the recipients had the relevant ligand, such as HLA-C2 or Bw4. This finding suggested that in the setting of T-cell-replete haploidentical transplantation, the alloreactive NK cells could be best predicted by the donor-activating KIR gene and the relevant KIR ligand in the recipient. This clinical observation was consistent with the recent basic findings that KIR2DS1-positive NK cells could mediate the alloresponses against the C2 HLA-KIR ligand group *in vitro* (Chewning *et al*, 2007; Marcenaro *et al*, 2011, 2013). This finding was also in accordance with the report from Gabriel *et al*, 2010 after autologous SCT, which found that the interaction between donor KIR3DS1 and HLA-Bw4 in recipients was predictive for increased NK-cell function, as assessed by the control of leukaemic relapse. In alloreactive NK-cell responses, KIR2DS1 expression represents a remarkable advantage because it allows for the efficient killing of C2/C2 or C1/C2 myelomonocytic DCs and T-cell blasts (Sivori *et al*, 2011; Marcenaro *et al*, 2013). However, to reduce the risk of relapse among 1277 patients with AML who underwent unrelated matched or single mismatched HSCT, the data published by

Venstrom *et al* (2012) supported the preferential selection of a KIR2DS1-positive donor if the donor had HLA-C1/C1 or C1/C2 and was not based on HLA-C in the recipient. Pittari *et al* (2013) also demonstrated NK-cell tolerance of self-specific activating receptor KIR2DS1 in individuals with the cognate HLA-C2 ligand. Therefore, the reason for these apparently discordant results might be the balance between the activating donor KIR gene in NK-cell education/tolerance induction, as well as the initiation of alloreactivity in NK cells post-transplantation. The induction of tolerance in NK cells that express activating receptors through chronic exposure to the ligand was described in mice (Tripathy *et al*, 2008). However, in the setting of haploidentical transplantation, the induction of tolerance in NK cells that express activating receptors remains unknown.

The contrasting effects of the missing self model between donors and recipients and between the activated donor KIR genes and the relevant KIR ligands in recipients on relapse in haploidentical transplantation precisely suggest that the presence of class I ligands for the donor-activating or donor-inhibitory KIR gene in the recipient might confer some protection against leukaemic relapse in T-cell-replete haploidentical transplantation. Acquisition of NK-cell activity including inflammatory cytokines production and cytotoxicity have a pivotal role in the graft-vs-leukaemia effect after allogeneic haematopoietic cell transplantation. Natural killer cells can only acquire full functionality post-transplantation when the NK cells have been shown to recognise self-MHC class I, a phenomenon referred to as 'licensing' or 'education' (Kim *et al*, 2005; Yawata *et al*, 2006, 2008; Yu *et al*, 2007; Sun *et al*, 2009; Sungur *et al*, 2013). The interaction of recipients class I ligands and donor-inhibitory KIR genes and activating KIR genes have important roles on the process of NK-cell education *in vivo* and the initiation of alloreactivity in NK cells post-haploidentical transplantation. Therefore, we hypothesis that KIR-HLA interactions and of how NK-cell education undergoes T-cell-replete haploidentical transplantation to dictate NK function would be helpful in revealing these apparently disparate results in the literature in the future. It would also be helpful to explain the contrasting effects of donor KIR2DS5 and donor KIR2DS3 on TRM and survival. However, this study was limited by not performing the NK functional recovery kinetics to explore the correlations between the educated/uneducated NK cells' reconstitution and the alloreactive NK cells' recovery *in vivo* post-T-cell-replete haploidentical transplantation.

In summary, the seemingly contrasting effects of alloreactive NK cells on relapse, using the missing self model or activated donor KIR genes, reflect that the presence of class I ligand in the recipient for the donor-inhibitory KIR gene or the donor-activating KIR gene could be an superior prognostic factor in preventing relapse. This study indicated that the presence of recipient class I ligands for donor-activating and donor-inhibitory KIR genes would promote NK-cell functional recovery during NK-cell education, thus conferring some protection against leukaemic relapse in T-cell-repleted, haploidentical transplantation, which would be worthy of future study. In addition, a large diverse cohort study should be conducted in the future in a prospective manner to confirm the effects of recipient HLA and donor KIR genotype associations on the clinical outcomes of transplantation.

ACKNOWLEDGEMENTS

This work was supported by the National Natural Science Foundation of China (grant nos. 81270644 and 81230013), the Major State Basic Research Development Program of China

(973 Program No. 2013CB733700), and doctoral funding from the Ministry of Education of China (grant no. 20110001110039), and partially supported by Collaborative Innovation Center of Hematology, China. We thank all of the core facilities at the Peking University Institute of Hematology for sample collection.
