Review

Cell death, clearance and immunity in the skeletal muscle

C Sciorati¹, E Rigamonti¹, AA Manfredi^{1,2} and P Rovere-Querini^{*,1,2}

The skeletal muscle is an immunologically unique tissue. Leukocytes, virtually absent in physiological conditions, are quickly recruited into the tissue upon injury and persist during regeneration. Apoptosis, necrosis and autophagy coexist in the injured/regenerating muscles, including those of patients with neuromuscular disorders, such as inflammatory myopathies, dystrophies, metabolic and mitochondrial myopathies and drug-induced myopathies. Macrophages are able to alter their function in response to microenvironment conditions and as a consequence coordinate changes within the tissue from the early injury throughout regeneration and eventual healing, and regulate the activation and the function of stem cells. Early after injury, classically activated macrophages ('M1') dominate the picture. Alternatively activated M2 macrophages predominate during resolution phases and regulate the termination of the inflammatory responses. The dynamic M1/M2 transition is increasingly felt to be the key to the homeostasis of the muscle. Recognition and clearance of debris originating from damaged myofibers and from dying stem/progenitor cells, stromal cells and leukocytes are fundamental actions of macrophages. Clearance of apoptotic cells and M1/M2 transition are causally connected and represent limiting steps for muscle healing. The accumulation of apoptotic cells, which reflects their defective clearance, has been demonstrated in various tissues to prompt autoimmunity against intracellular autoantigens. In the muscle, in the presence of type I interferon, apoptotic myoblasts indeed cause the production of autoantibodies, lymphocyte infiltration and continuous cycles of muscle injury and regeneration, mimicking human inflammatory myopathies. The clearance of apoptotic cells thus modulates the homeostatic response of the skeletal muscle to injury. Conversely, defects in the process may have deleterious local effects, guiding maladaptive tissue remodeling with collagen and fat accumulation and promoting autoimmunity itself. There is strong promise for novel treatments based on new knowledge of cell death, clearance and immunity in the muscle.

Cell Death and Differentiation (2016) 23, 927–937; doi:10.1038/cdd.2015.171; published online 12 February 2016

Facts

- M1/M2 timely transition triggered by the recognition of apoptotic cells in the skeletal muscle is a key to tissue homeostasis.
- Regulatory T lymphocytes accumulate in the injured skeletal muscle and are instrumental for healing, whereas conventional CD4⁺ or CD8⁺ T lymphocytes are found in persistently inflamed muscles.
- Defective clearance of dead cells prompts maladaptive muscle remodeling with deposition of collagen and fat.
- The generation of apoptotic cell-derived autoantigens induces autoimmunity and self-maintaining immune-mediated tissue damage in the presence of type 1 interferon.

Open Questions

Which are the phagocytic receptors and bridging molecules involved in the recognition of apoptotic cells in the muscle and how do they influence the outcome of the clearance?

- Do regulatory T cells control immune cell function in muscle and physiologically restrict autoimmunity in the tissue?
- Would it be possible to revert the noxious effects of maladaptive tissue remodeling and of autoimmunity by prompting debris disposal?

Unique Immune Privileges of the Skeletal Muscle

Immune privilege is an evolutionary conserved adaptation that protects vulnerable tissues from the noxious effects of inflammation. Allogeneic transplanted tissues are not rejected

Figure 1 Physiology of skeletal muscle. Skeletal muscles as organs consist of muscle fibers bound by connective tissue. Skeletal muscles are attached to bone by tendons composed of connective tissue. Each muscle is wrapped in a sheath of connective tissue called the epimysium that allows a muscle to contract and move while maintaining its structural integrity. Bundles of muscle fibers, called fascicles, are covered by the perimysium. Inside each fascicle, each muscle fiber is encased in a thin connective tissue layer called the endomysium that contains the extracellular fluid and nutrients to support the muscle fiber. Nutrients are supplied via blood vessels to the muscle tissue. In close proximity to the muscle fibers are the satellite cells that are the main source of myogenic precursors. A large number of cells are present in the interstitial spaces of skeletal muscle and together with satellite cells they sustain the life-long maintenance of muscle tissue

when transplanted in privileged sites, or immunological 'sanctuaries', that are often crucial for the survival either of the individual (the eye and the brain) or of the species (gonads, the pregnant uterus).^{1,2} The immune privilege could provide an evolutionary advantage, making immune responses less likely to cause irreversible damage in sites in which cells cannot be easily replaced.³ The immune privilege involves systemic and local regulatory events. They include the physical separation from the immune system by anatomical or functional barriers, such as the blood–brain or the blood–retina barriers,⁴ a limited constitutive expression of major histocompatibility complex (MHC) molecules, the absence of resident professional antigen-presenting cells (APCs) and a scant lymphatic drainage. When barriers are disrupted, immune-privileged sites initiate regulatory processes that: (1) limit the extent of immune activation and (2) select the potentially less damaging immune response. This has been well characterized in particular for the ocular immune privilege⁵ but plays a role in the homeostasis of other immunologic sanctuaries, including the brain.⁶

The skeletal muscle is the largest cellular compartment of the body, characterized in physiological conditions by a relatively slow turnover. It is an immunologically unique tissue or a 'nonclassical' immunological privileged site. It is not endowed with anatomical barriers and the lymphatic vasculature is well represented. However, immune cells, including APCs, are in physiological conditions virtually absent and the tissue expression of MHC class I or class II

molecules is limited (Figure 1). Moreover, the outcome of sterile inflammation in the skeletal muscle appears to be the recruitment of alternatively activated macrophages and of regulatory T cells that play non-redundant roles in muscle regeneration and possibly contribute to limit autoimmunity^{7,8} (see below). Thus, muscle inflammation comprises signals that possibly contribute to initiate tissue regeneration and to terminate it in a timely manner once the tissue has healed and its homeostatic function is no longer required. Data in recent years indicate that the recognition and the clearance of cells dying in the skeletal muscle are critical for muscle homeostasis and maintenance of tolerance. This paradigm, even if exquisitely unique of muscle immunobiology, could be important to understand the link between inflammation and tissue repair at other anatomical sites.

The Prey: Cell Death in the Skeletal Muscle

DNA fragmentation, caspase activation and mitochondria apoptosis-associated protein release have all been described in the muscle as a consequence of trauma, hindlimb unloading, disuse, genetic defect including dystrophy or age-associated sarcopenia.^{9–12} The stereotyped sequence of events that characterize apoptosis of single cells can hardly account for the complexity of the programmed death of multinucleated myofibers. Programmed death causes the selective removal of individual targeted myonuclei and of 'myonuclear domains', the limited areas of cytoplasm that

individual myonuclei support.^{13,14} Muscle fiber segment with TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labeling)-positive nuclei alongside intact nuclei has been described.¹⁵ Myonuclear apoptosis might contribute to skeletal muscle atrophy (however, see Bruusgaard *et al.*¹⁶). Apoptosis in response to acute muscle injury appears more straightforward and is modulated by metabolic pathways involving ganglioside biosynthesis.¹⁷

Myofibers also dispose of damaged organelles by autophagy that is activated during muscle atrophy and variably contributes to the loss of muscle mass.^{18,19} The apoptotic process in the skeletal muscle might be preferentially activated to face defective autophagy,²⁰ suggesting that the two processes are intermingled. Both apoptosis and autophagy possibly contribute to age-related sarcopenia that is associated with loss in the overall mass and with a reduced number of myofibers.^{14,21–25}

Disorganization of myofibrils with Z line loss, mitochondrial swelling and sarcolemmal disruption are hallmarks of the skeletal muscle necrosis. Intracellular moieties including myoglobin, creatine phosphokinase (CK) and other sarcoplasm proteins are released into the bloodstream.²⁶ During intense exercise, on-going cell death and DNA fragmentation together with undamaged sarcolemma and preserved contractile proteins are detectable in the muscle.^{27,28} Necrosis-released enzymes are found in human blood after eccentric muscular contractions as those performed during marathon, weight-bearing exercises and downhill running.^{29,30} Serum CK might not only reflect fiber disruption. In highly energy-demanding conditions, fibers might prevent the bioenergetic collapse by the expulsion of ATP-consuming enzymes. CK would be redistributed to membrane blebs whereas bleb extrusion would allow expulsion of the enzyme.³¹

Acute sterile injury of the skeletal muscle results in the early mitochondrial generation of reactive oxygen species (ROS). These organelles undergo rapid disruption at later time points and non-mitochondrial sources of ROS generation emerge. In parallel, an antioxidant response is activated in both regenerating fibers and leukocytes that express high levels of free thiols and antioxidant enzymes.³² Intracellular damage-associated molecular patterns (DAMPs) are also released after injury, and their inflammatory action in the extracellular environment might contribute to recruit inflammatory phagocytes, to activate them and to prompt the immunogenicity of dying cells.³³ The prototypical DAMP, high-mobility group box 1 (HMGB1), is a redox-sensitive moiety that in a predominantly reduced environment preferentially promotes leukocyte recruitment, upon formation of heterocomplexes with the chemokine (C–X–C motif) ligand 12 chemokine. The partially oxidized isoform in contrast preferentially activates the Toll-like receptor-4 (TLR4) with downstream chemokine and cytokine release.^{34–36} The terminally oxidized sulfonate isoform appears even less able to attract leukocytes or to elicit cytokines, even if it maintains the ability to modulate neutrophil integrin transactivation and degranulation.³⁷

HMGB1 is weakly expressed in healthy muscles.³² The expression increases during regeneration in parallel with the antioxidant response in both fibers and leukocytes. A reduced

environment may be important to maintain HMGB1 bioactivity. Indeed, oxidation abrogates both muscle stem cell migration in response to HMGB1 and their ability to differentiate into myofibers *in vitro*.^{25,32,38,39} The early antioxidant response in regenerating muscle might limit HMGB1 oxidation, thus allowing the timely recruitment of leukocytes, the activation of muscle stem cells, the reconstitution of the vasculature and the eventual successful muscle regeneration.^{25,39} Of importance, HMGB1 expression is modulated upon persistent immune-mediated damage of the muscle during inflammatory myopathies, suggesting that its generation might contribute to the natural history of these conditions.^{40,41}

Apoptosis, necrosis and autophagy represent extremes of the response of the muscle to injury and often coexist (Figure 2). They have been extensively studied in animals exploiting various experimental models of damage. Most models recapitulate the sequence of injury/inflammation/regeneration, even if they are characterized by different patterns of tissue remodeling, kinetics of repair and leukocytes preferentially involved. Table 1 summarizes the most widely used injury models.

Cell death has also been extensively studied in patient specimens and in experimental models of neuromuscular disorders, including inflammatory myopathies, metabolic and mitochondrial myopathies, dystrophinopathies and drug-induced myopathies.^{42,43} Muscle dystrophies are paradigmatic examples of muscle fiber loss by necrosis,⁴⁴ even if segmental apoptosis occurs with areas of caspase expression and TUNEL positivity adjacent to necrotic zones.⁴⁵ Apoptosis has been described in inflammatory myopathies,^{46,47} at least in some cases as a result of the cytotoxic action of T lymphocytes. Finally, the generation of neutrophil extracellular traps (NETs), an event strictly associated with the activation of autophagy pathway in inflammatory leukocytes⁴⁸ and modulated by the recognition of apoptotic cells,⁴⁹ has been described in the muscle upon ischemia–reperfusion injury.⁵⁰ Further studies will evaluate the relevance of NET contribution to muscle remodeling during autoimmune diseases and in homeostatic conditions.

Besides myonuclear apoptosis and myofiber necrosis, other cells die in the midst of the inflamed skeletal muscle (Figure 2). This is specifically the case of muscle stem cells and of stromal cells including fibroadipogenic progenitors (FAPs). Skeletal muscle injury is known to be associated with the early proliferation of the best-characterized muscle stem cells, the satellite cells. A fraction of proliferating satellite cells die, as assessed by positivity of the TUNEL assay and by the cleavage of poly ADP ribose polymerase, via a pathway involving the Foxo3 transcription factor.⁵¹ Specific pathways have apparently been generated to modulate the ability of satellite cells to survive in response to various environmental stimuli including those related to the angiotensin 1/Tie2 system,⁵² to the member of the Melanoma-associated antigen D1 family of proteins, necdin,⁵³ and to the thyroid hormone.⁵¹ FAPs comprise multipotent mesenchymal progenitor cells⁵⁴ that are a source of matrix-secreting activated myofibroblasts in the skeletal muscle.⁵⁵ Their fate appears to be finely regulated by the extent and by the characteristics of the inflammatory response (see below) and their regulated death and clearance is possibly critical to

prevent tissue fibrosis. Defective FAP clearance reflects and contributes to the maladaptive remodeling of the skeletal muscle.⁵⁶

Inflammatory leukocytes represent another source of dying cells in the damaged/regenerating skeletal muscle. Their fate has not been characterized in detail. The kinetics

of their accumulation in the tissue and the insight derived from the studies of apoptosis in other inflamed tissues strongly imply that regulated death and phagocytic clearance of infiltrated leukocytes are a prerequisite for appropriate resolution of the inflammatory response and possibly for repair of the injured tissue.⁵⁷

Figure 2 Cell death and phagocytic clearance in skeletal muscle. Muscle fibers die through apoptosis, necrosis and autophagy. Skeletal muscle death has been described in parapsychological conditions and is a hallmark of several muscle diseases. Besides muscle fibers, other cells die after injury. A fraction of proliferating muscle stem cells as well as stromal cells and FAPs undergo apoptosis after muscle healing. Another source of dying cells is the inflammatory leukocytes that infiltrate the muscle after injury. Leukocytes, especially macrophages, are also responsible for the clearance of apoptotic cells, indispensable for the resolution of inflammation and tissue repair. FAPs also contribute to the phagocytosis of cellular debris

Table 1 Features of commonly employed experimental models of acute muscle damage

Injury	Model	Muscles	Main characteristics	Reference
Mechanic	Laceration	Soleus, gastrocnemius	Severe fiber breakdown innervation involvement, inflammation, slow regeneration, scar formation and incomplete recovery may occur	134,135
	Crush	Gastrocnemius, tibialis anterior, soleus	Fiber blunt followed by necrosis, edema-induced spacing, hemorrhage and inflammation, exercise-facilitated regeneration, extracellular matrix deposition	136–139
	Strain (electric stimulation, traction, forced exercise)	Gastrocnemius, quadriceps, hamstring, soleus	Fiber tears and sarcolemma breakdown, hemorrhage, tendon involvement, extracellular matrix deposition, inflammation	140–143
	Freezing	Gastrocnemius tibialis anterior	Edema, inflammation, fast regeneration	144,145
	Ischemia/reperfusion	Leg muscles	Inflammation, hemorrhage, slow regeneration	146,147
	Atrophy (limb suspension, denervation or spinal cord injury, antigravity)	Leg muscles, gastrocnemius	Muscle mass loss, fiber size reduction, shift in fiber type, nuclei loss, autophagy	148–150
Chemical	Toxin injection	Tibialis anterior, quadriceps gastrocnemius, soleus	Sarcolemma degradation with intact basal lamina, calcium overload, inflammation	26,151
	Glycerol injection	Tibialis anterior	Necrosis of muscle fibers, vacuolar changes, inflammation, adipose tissue infiltration	152,153

Figure 3 Skeletal muscle healing depends on inflammation. Efficient skeletal muscle healing occurs in overlapping phases of inflammation, proliferation and remodeling. Upon muscle injury, satellite cells activate, start proliferating and subsequently fuse and differentiate into new myotubes that later grow and replace damaged muscle. Several cell types modulate both proliferation and differentiation of satellite cells, in particular inflammatory cells that are recruited from the blood. Neutrophils and eosinophils firstly arrive in the damaged tissue. Neutrophils release ROS and proteolytic enzymes that further amplify the damage and local inflammation. Eosinophils induce the proliferation of FAPs that in turn contribute to debris clearance and satellite cell proliferation. Shortly after, monocytes extravasate in the injured areas where they differentiate in proinflammatory M1 macrophages that clear cellular debris and stimulate satellite cell proliferation. This initial Th1-driven inflammation is later overcome by an anti-inflammatory response that coincides with a M1-to-M2 switch. M2 macrophages and Th2 cytokines (IL-10, IGF-1, TGFβ) reduce local inflammation and contribute to myoblast fusion and new myofiber formation. A variety of intrinsic and extrinsic factors are responsible for macrophage phenotypic polarization; pericytes and Treg cells represent an additional layer of control. Pericytes sustain the ability of macrophages to clear apoptotic cells and promote the expression of genes associated with their alternative activation. Treg cells begin to accumulate in damaged muscle within days after injury and contribute to muscle healing at several levels. They promote M1-to-M2 switch, increase satellite cell proliferation and modulate effector T cell (CD8+ or B cells)

The Regeneration of Injured Muscles Depends on Inflammation

Skeletal muscle has a remarkable capability to regenerate. Main players are the satellite cells, localized between the basal lamina and the fiber membrane.⁵⁸ Satellite cells leave the quiescent state, characterized by expression of the paired-box protein Pax7,⁵⁹ and proliferate, eventually yielding myoblasts that express the MyoD regulatory factor.⁶⁰ After multiple cell divisions, myoblasts terminally differentiate and fuse, forming small centronucleated fibers that gradually grow in size providing complete muscle regeneration.^{60–63}

Leukocytes are quickly drawn into the damaged muscle. An epimysial/perimysial connective tissue-resident macrophage population possibly endowed with antigen-presenting capacity and with the ability to migrate into the draining lymph would be

in charge of the early attraction and local activation of inflammatory cells.⁶⁴ Other sentinels of tissue injury, including platelets and mast cells,⁶⁵ are likely to contribute. Leukocytes are constantly detectable in the injured muscle while the regeneration process occurs. They disappear once the tissue is completely healed.⁶⁶ Polymorphonuclear cells, including neutrophils and eosinophils, are the first leukocytes to be recruited in the damaged tissue. Shortly after, macrophages accumulate and subsequently become the dominant leukocyte population.^{67,68} Macrophages are responsible for the removal of cellular debris, most likely including those derived from dying eosinophils and neutrophils (see above). Their ability to perceive the characteristics of the tissues that dramatically change from the early injury throughout regeneration and eventual healing and to coordinate the activation and the function of stem cells is critical for muscle

homeostasis^{69–71} (see below). Lymphocytes also accumulate in the injured skeletal muscle. In normal conditions they mostly comprise regulatory T cells and are instrumental for healing. This action is mediated by the productive interaction with muscle stem cells.^{7,8} In contrast, the accumulation of conventional CD4⁺ or CD8⁺ T lymphocytes reflects persistent inflammatory and immune-mediated injury, such as that taking place as a consequence of muscular dystrophy or inflammatory myopathies.^{72,73} Figure 3 depicts some cellular players of muscle regeneration.

Muscle stem cells fail to activate their regenerative potential in the absence of the inflammatory response.^{66,70,74} The release of DAMPs/alarmins as a consequence of cell death and of immune cell activation might be important in the reciprocal activation/regulation of immune and of muscle stem/progenitor cells. The availability of novel elegant genetic inducible cell-fate mapping models will be valuable for the better understanding of the overall scenario. In skeletal muscle, immune responses depend almost completely on recruited inflammatory cells that decode the need of the tissue for healing and broadcast the news to resident stem/progenitor cells. Thus, the characteristics of immune cell activation are critical.

The Predators: Macrophages Scavenge Muscle Debris

Despite the significant amount of cell death that occurs in inflamed muscle, under physiological conditions cell remnants are extremely rare, indicating that the debris disposal mechanisms are effective. Macrophages are essential. Their depletion results in the persistence of cell remnants, deriving either from necrotic fibers, dying progenitor cells or inflammatory leukocytes. Moreover, upon depletion of macrophages muscle regeneration is severely compromised (reviewed in Bosurgi *et al.*⁷⁰ and Tidball and Villalta⁷¹). Macrophages and muscle regeneration are therefore closely associated. The dissection of the macrophage plasticity in the tissue has allowed in the past years to define more precisely the hierarchy of events in the maintenance of muscle homeostasis.

Macrophages that infiltrate the tissue at early time points after injury are classically activated inflammatory macrophages, also referred to as 'M1' cells. They generate inflammatory cytokines and sustain the activation and the proliferation of muscle stem cells.⁷⁵ 'Alternatively activated' or 'M2' macrophages predominate during the resolution phases of the damage when they regulate the termination of the inflammatory responses.^{69,76} Monocyte-derived macrophages undergo dynamic transitions between M1 and M2 and this timely transition is increasingly felt to be the key to muscle homeostasis.^{77,78}

MAP kinase phosphatase-1 (MKP-1) regulates cell remnant disposal, macrophage transition and muscle healing.^{79,80} Gene expression analyses on sorted MKP-1^{-/-} muscle macrophages suggest that MKP-1 regulates the inflammatory response as well as the macrophage polarization via p38 MAPK downregulation. Another enzyme, the AMP-activated protein kinase (AMPK)- α 1, which 'senses' the cellular energy levels, also regulates the inflammatory status of macrophages. AMPK- α 1-deficient macrophages fail to undergo an alternative M2 activation upon the recognition of apoptotic cells,⁸¹ suggesting a relationship between macrophage

polarization and debris disposal. Studies on the cAMP response element-binding protein (CREB), a transcription factor involved in the upregulation of M2-associated genes, further strengthen the existence of a cause-effect relationship between recognition of apoptotic cells and acquisition of the macrophage ability to guide muscle stem cell regenerative potential. Deletion of CREB-binding sites from the C/EBP β gene promoter indeed blocks the downstream induction of regulatory genes. Debris are effectively cleared but muscle fiber regeneration is severely jeopardized.⁷⁶ In contrast, other crucial pathways, such as those coordinated by myeloid hypoxia-inducible factors, are apparently dispensable for M1/M2 shift and muscle healing after sterile injury.⁸² Of importance, other cells, including eosinophils and FAPs, are apparently involved in the clearance of necrotic muscle debris in experimental models^{56,83} (Figure 2). Even myoblasts *in vitro* appear to be endowed with the ability to internalize apoptotic myoblasts.⁸⁴ The actual contribution of these unconventional phagocytes in physiological conditions and their impact on the skeletal muscle immunobiology will require further study.

The expression of phagocytic tags by dying cells is fundamental for their recognition and clearance.^{85–88} Relatively little is known on the role of phagocytic tags in the skeletal muscle. Exposure of anionic phospholipids, such as phosphatidylserine (PS), is among the best-characterized events involving in apoptotic cell recognition.⁸⁹ Induction of fusion appears to cause death of a fraction of myoblasts.⁹⁰ Intriguingly, PS recognition is important for the formation of myotubes.^{84,91,92} *In vivo*, expression of the well-characterized PS receptor BAI1 is required for muscle regeneration, further strengthening the link between cell death in the tissue, exposure and recognition of PS and successful tissue healing.⁸⁴

Phagocytes uphold muscle stem cell differentiation and function. Conversely, muscle stem cells influence macrophages. This is the case for vessel-associated muscle stem cells (also referred to as mesoangioblasts), myogenic precursors that express pericyte markers and cross vessel walls,^{69,93,94} they sustain the ability of macrophages to clear apoptotic cells and promote the expression of genes associated with their alternative activation.⁹⁵

Outcomes of Defective Apoptotic Cell Clearance: Maladaptive Muscle Remodeling with Ectopic Tissue Deposition

The skeletal muscle homeostasis is in most cases maintained upon injury. However, in some cases the original damaging noxa cannot be removed, such as in muscular dystrophies⁹⁶ or in immune-mediated inflammatory myopathies (IIM).⁹⁷ As a consequence, inflammation persists and repeated cycles of necrosis and regeneration ensue, eventually causing the substitution of myofibers with noncontractile elements such as fat, fibrotic tissue or bone.⁹⁸

Acellular lipid droplets and adipocytes, defined based on triglycerides and cholesterol ester content and by the expression of peroxisome proliferator-activated receptor γ 2, perilipin, leptin, adiponectin and fatty acid-binding protein 4, account for the muscle fat.⁹⁹ Intra- and intermuscular fat is a histopathological hallmark of persistently damaged

Figure 4 Adaptive and maladaptive muscle remodeling. Skeletal muscle homeostasis is in most cases maintained upon injury. Macrophages and FAPs contribute to effective debris disposal and together with Treg cells they sustain satellite cell proliferation/differentiation and contribute to the resolution of inflammation (left panel). However, in some cases the original damaging noxa cannot be removed and maladaptive muscle remodeling takes place. In particular, in inflammatory myopathies skeletal muscle is characterized by persistent inflammation with recruitment of autoreactive T cells (CD4+/CD8+), production of autoantibodies and frequently the substitution of myofibers with noncontractile elements such as fat and fibrotic tissue. We propose that the simultaneous presence of inflammation, apoptotic myoblasts and type I interferon could participate into the initiation of a self-sustaining autoimmunity (right panel)

and inflamed muscles. Cells of mesenchymal origin yield adipocytes *in vitro* and *in vivo*, including satellite cells, fibroblasts, myoendothelial cells, pericytes, mesoangioblasts, PW1-expressing cells and FAPs.⁹⁹

FAPs sustain satellite cell-driven myogenesis or directly differentiate into myoblasts in physiological conditions.⁵⁴ When regeneration fails because of satellite cell defect^{55,100} and/or inadequate inflammatory response,⁸³ they generate adipocytes or differentiate into myofibroblasts. Myofibroblasts physiologically proliferate and synthesize extracellular matrix as scaffold to new fibers in reparative myogenesis. Upon injury resolution they induce matrix remodeling and degradation before undergoing apoptosis.¹⁰¹ The counterpart of this event, that is, a self-perpetuating matrix deposition, eventually causing fibrosis, is characteristic of the persistently inflamed skeletal muscle.^{56,102–104}

Heterotopic ossification may occur after severe traumatic skeletal muscle damage or neurological injury¹⁰⁵ and seems

to result from inappropriate differentiation of mesenchymal progenitors. Persisting inflammation, inadequate phagocytosis and bone morphogenetic proteins activation are all thought to contribute.^{106,107} A rare genetic disorder, *fibrodysplasia ossificans progressiva*, associated with the activating mutation in the bone morphogenetic protein type I receptor ALK2 clearly highlights the link.¹⁰⁸

Outcomes of Defective Apoptotic Cell Clearance: Autoimmunity

IIM leads to disability, decreased quality of life and increased mortality.¹⁰⁹ Persistent inflammation with recruitment of autoreactive T cells characterizes the skeletal muscle.^{110,111} Available evidence strongly supports the autoimmune underpinnings of IIM and commonly targeted autoantigens include proteins involved in DNA transcription or protein synthesis, such as the histidyl-tRNA synthase (HisRS).^{73,112–114} Regenerating fibers appear a preferential

source of autoantigens, suggesting that regeneration plays an important role in initiating and/or perpetuating the disease process.¹¹⁴ However, the signals that confer immunogenicity to a rather limited set of ubiquitously expressed intracellular antigens have only partially been characterized. Modifications of the autoantigens, including enhanced expression, altered distribution and/or access to phagocytes/APCs for processing, might be mechanistically important. Adjuvant signals selectively generated during various forms of inflammation might further influence the antigen presentation in given tissues. In turn, this might contribute to the onset and the maintenance of autoimmune responses targeting ubiquitously expressed antigens while selectively damaging particular tissues, such as the skeletal muscle in IIM.¹¹⁵

We have recently observed that despite its abundant expression in myogenic precursors within inflamed muscles, HisRS is not by itself fully immunogenic. Lack of immunogenicity could depend on: (1) the lack of access of an intracellular moiety to APCs that must process and cross-present epitopes to autoreactive T cells; and/or (2) a still noncharacterized action in the maintenance of tolerance of Treg populations that are physiologically recruited during regeneration of the tissue.^{7,8}

Apoptotic HisRS-expressing myogenic precursors might represent a preferential substrate for phagocytic uptake and processing by APCs. In fact, several observations support the relevance of the link between apoptosis and autoimmunity that has been extensively studied in other contexts. For example, the programmed death of keratinocytes influences the structure and the pattern of expression of intracellular antigens that are selectively redistributed to apoptotic bleb structures.^{116,117} In turn, apoptotic cells represent immunogenic substrate for uptake and presentation to autoreactive lymphocytes.

Protective immunity targeting viral and neoplastic intracellular antigens and the establishment of self-sustaining systemic autoimmune diseases are among the *in vivo* consequences of the T-cell activation.^{118–124} Indeed, treatment with cancer cells killed with lethal doses of doxorubicin vaccinates mice against a subsequent challenge with living neoplastic cells of the same type and leads to the identification of the ‘immunogenic cell death’.^{125,126} Various signals and processes influence the immunogenic outcome of the cell death including the action of DAMPs, like cell surface-exposed calreticulin, extracellular ATP and HMGB1, and the processes that make the DAMP available in the extracellular environment, such as endoplasmic reticulum (ER) stress, autophagy and plasma membrane permeabilization disruption upon necrosis. Implications of these concepts are being actively studied in particular in the oncology field and consensus guidelines for the detection of immunogenic cell death have been recently published.¹²⁷

Of interest, virtually all the processes involved in facilitating DAMP release and biological action are well characterized in the inflamed skeletal muscle: HMGB1 is a critical signal not only in the physiological remodeling of the injured tissue (see above), but also plays well-characterized role in IIM.^{41,128} Autophagy is critically involved in the physiologic response of the muscle to stressful conditions (see above). Impaired autophagosome maturation with consequent accumulation of

multiprotein aggregates is a key factor in the myofiber degeneration characteristic of inclusion body myopathy, while evidence of sustained autophagic flux is detectable in IIM muscles.¹²⁹ Upregulation of the expression of MHC class I molecules in skeletal muscle fibers is an early feature of IIM and ectopic expression of the molecule induced ER stress response and resulted in a disease that shares several features with human IIM.^{130,131}

Considering that muscle injury and the associated inflammatory response represent rather common event *in vivo*,¹⁰⁹ the relative rarity of IIM indicates that a number of events must simultaneously occur to set the stage for self-sustaining autoimmunity. We have recently observed that apoptotic myoblasts are immunogenic only if appropriate adjuvants are provided in the injured/regenerating muscle.¹³² Specifically, apoptotic myoblasts in the presence of stimuli activating TLR7-dependent inflammatory pathways and the generation of type I interferon, a key cytokine expressed in IIM patients and physiologically produced by myogenic precursors,¹³³ induce the production of anti-HisRS antibodies, linked to persistent leukocyte infiltration of the tissue, reproducing several features that occur in the tissue of patients with IIM¹³² (Figure 4).
