Preferential killing of human lung cancer cell lines with mitochondrial dysfunction by nonthermal dielectric barrier discharge plasma

K Panngom^{1,2}, KY Baik^{*,2}, MK Nam³, JH Han³, H Rhim³ and EH Choi^{*,1,2}

The distinctive cellular and mitochondrial dysfunctions of two human lung cancer cell lines (H460 and HCC1588) from two human lung normal cell lines (MRC5 and L132) have been studied by dielectric barrier discharge (DBD) plasma treatment. This cytotoxicity is exposure time-dependent, which is strongly mediated by the large amount of H₂O₂ and NO_x in culture media generated by DBD nonthermal plasma. It is found that the cell number of lung cancer cells has been reduced more than that of the lung normal cells. The mitochondrial vulnerability to reactive species in H460 may induce distinctively selective responses. Differential mitochondrial membrane potential decrease, mitochondrial enzymatic dysfunction, and mitochondrial morphological alteration are exhibited in two cell lines. These results suggest the nonthermal plasma treatment as an efficacious modality in lung cancer therapy.

Cell Death and Disease (2013) 4, e642; doi:10.1038/cddis.2013.168; published online 23 May 2013

Subject Category: Cancer

One of the most important questions in cancer therapy is the selective killing of cancer cells without damaging normal cells. Generally, cancer cells are known to generate more reactive oxygen species (ROS) and be more damaged by exogenous ROS.¹ Therefore, researchers have searched ROS generating drugs for preferential cytotoxicity in cancer cells.^{2,3} In that sense, the nonthermal plasma had been introduced as a tool with a potential of shifting current paradigm of cancer treatment.⁴ Nonthermal plasma generates various reactive species including ultraviolet, charges, and reactive nitrogen species as well as ROS in cell culture media.^{5–7}

The biomedical application of nonthermal plasma is emerging field. Its potential has been demonstrated in various applications such as sterilization of infected tissues, acceleration of wound healing, induction of blood coagulation, delicate surgery, and so on.⁵ Among these, the most intensively studied one may be its application to anticancer therapeutics.⁸ Reactive species generated from nonthermal plasma has successfully induced apoptosis through DNA damage and mitochondrial dysfunction in cancer cell lines.^{8–11} Moreover, a few previous studies demonstrated selective plasma-induced easy detachment of cancer cells to normal cells.^{4,12} However, there is still no report comparing the nonthermal plasma-induced cytotoxicity in cells from the same organ. As cancer cells from different organs have differential responses to the same plasma stimuli,¹³ cells originated from same organ should be used for sounding out the potential of plasma cancer therapy.

In this experiment, we examined a cancer cell line H460 and normal cell lines MRC5 and L132 from human lung. Lung cancer is the most lethal cancer, which is a leading cause of human death in both men and women.^{3,14} Among two types of lung cancer cells, non-small cell lung cancer kills people > 85% and has very complex causes.^{3,15} Importantly, lung cancers have propensity to metastasize early,¹⁴ have drug resistance and poor target specificity,³ and frequently overexpress antiapoptotic protein, such as bcl-xL¹⁶ and survivin.¹⁴ Therefore, it is worth to try new modality in highly challenging lung cancer therapy, and the nonthermal plasma can be a strong candidate as Kim *et al.*¹⁷ showed in precise micro-plasma jet device.

Herein, we present the preferential killing of lung cancer cells to lung normal cells by nonthermal DBD plasma treatment. This differential sensitivity is shown to be strongly related to the mitochondrial dysfunctions, such as morphological changes, reduction in mitochondrial metabolic activity, and reduction in mitochondrial membrane potential (MMP). This first report of preferential killing of human lung cancer cells possibly opens new lung cancer therapy by using nonthermal plasma.

Results

The amount of H₂O₂ and NO_x in culture media. Figure 1a is a schematic diagram of dielectric barrier discharge (DBD) plasma device used in this experiment. The DBD plasma consists of upper electrode made from silver and lower

Figure 1 Schematic diagram of DBD plasma device and its time-dependent effects on cell culture media. (a) The device consists of silver electrode, dielectric glass, and stainless steel mesh electrode. The distance between DBD device and cell culture plate is ~4 mm. (b) The temperature of DBD plasma device reaches up to 35.5 °C after 5 min exposure. (c) The pH of DMEM media increases 0.8 after 5 min exposure. (d) H₂O₂ (136 μM) is generated after 5 min exposure. (e) NO_x (3.4 mM) is generated after 5 min exposure

electrode made from stainless steel mesh. The interspacing distance between meshes is about 2 mm. The electrical power of 5.7 W has been supplied to the upper and lower electrodes to generate the atmospheric pressure nonthermal plasma. Here the airborne radicals from the plasma have been supplied to the cell culture media. During plasma exposure for 5 min, the temperature of media raised up to 35.5 °C (Figure 1b) and the pH of media increased up to 8.2 (Figure 1c). Although we do not use air blowing into cell culture media, our DBD plasma device can generate significant amount of H₂O₂ and NO_x in media. Figures 1d and e showed the amount of H₂O₂ and NO_x in cell culture media after plasma treatment. The amount of H₂O₂ increased to 61.28, 87.61 and 136.11 μM, following 1, 3 and 5 min exposure, respectively. The NO_x quantity increased to 0.85, 2.46 and 3.39 mM for 1, 3 and 5 min exposure, respectively. The amount of H₂O₂ and NO_x depend on the plasma treatment time, which should be related to time-dependent toxic effects of plasma treatment on cells.

Cell number. Figure 2a shows typical phase contrast microscopic images of cells after 24 h from the nonthermal DBD plasma exposure. The decrease of cell number with exposure time is clearly shown in all cell lines. Most H460 cancer cells after 5 min exposure even failed to attach on the

surface and became dead. For quantitative comparison, we counted cell numbers by using hemocytometer during 3 days' incubation, and the number ratio to every day control was plotted in Figure 2b. The cell number ratio was significantly decreased even in 1-min plasma-treated H460 cancer cells ($P < 0.01$), but it was not significant in MRC5 and L132 normal cells ($P > 0.05$). Moreover, the relative cell number to control is significantly decreasing following incubation day in H460, which can be expected from the reduced colony size of H460 in Figure 2a and also the cell cycle arrest in G₂/M state as shown in Figure S2 (supporting information). Figure 2c shows comparison of survival rate among two lung cancer cell lines (H460 and HCC1588) and two lung normal cell lines (MRC5 and L132) after 1 min plasma exposure. Normal cell lines have survived more than cancer cell lines under 1 min plasma exposure. Although longer time exposure induced more cell death in all cell lines, normal cells should have higher durability to plasma treatment.

Cellular and mitochondrial morphology. The surviving cells after plasma exposure adhered to the surface with slightly different morphology as shown in Figures 3a and c. The plasma-treated H460 showed bumpy boundary and localized focal adhesions, and the plasma-treated MRC5 showed wider adhesion with losing their initial spindle shape. The enlarged images show that actin fibers became shortened and localized near membrane in H460, and actin fibers were reorganized following their wider morphology in MRC5 (Supplementary Figure S3, supporting information).

At the same time, plasma treatment induced morphological changes of mitochondria in both H460 and MRC5 as shown in Figures 3b and d. In plasma-exposed cells for <3 min, mitochondria are rod-shaped and form tubular networks around nucleus. However, 5 min plasma-exposed cells show swollen or fragmented mitochondria. Moreover, it is notable that the mitochondria in 5 min plasma-treated H460 became giants and mitochondria in MRC5 became smaller, which should come from improper fusion and uncontrolled fission, respectively. These morphological changes in mitochondria and cytoskeletons strongly support that the cell death induced by DBD nonthermal plasma should not be mediated by necrosis.^{18,19}

Apoptosis. To check whether cell death induced by plasma is apoptosis, we stained cells with Annexin V, an early apoptotic indicator. In Figure 4a, enhanced fluorescent intensity of Annexin V shows the increase of apoptosis ratio in plasma-treated cells in both cell lines. Besides, we found that the apoptosis ratio depends on cell type as well as plasma exposure time. Among two cells, H460 showed a higher intensity of Annexin V at any plasma exposure time. In addition, when we stained them with propidium iodide (PI) dye together, we found that H460 undergoes apoptosis at a faster rate than MRC5 (Supplementary Figure S4, supporting information). When many H460 cells were stained by both Annexin V and PI dyes under H₂O₂ stimulus, MRC5 cells were stained only by Annexin V under the same H₂O₂ stress. H460 cells showed higher late apoptosis rate under plasma treatment as well, which is consistent with higher cell death

Figure 2 DBD plasma effects on cell death of lung cancer cells (H460 and HCC1588) and lung normal cells (MRC5 and L132). (a) The bright field images of H460, MRC5, and L132 at 1 day after plasma exposure. All scale bars are 100 μ m. (b) The relative cell numbers to control showed exposure time-dependent and incubation time-dependent death rate. H460 showed more severe lethality than MRC5 and L132 by nonthermal DBD plasma treatment. (c) Survival rate of two lung cancer cell lines and two lung normal cell lines after 1 min plasma treatment was compared during 3 days' incubation. Students' *t*-test was performed to control (* denotes $P < 0.05$ and ** denotes $P < 0.01$)

rate. However, we found that the lung normal cell MRC5 became smaller until 3 min plasma exposure, but became bigger in cell size after 5 min plasma treatment. As shown in the flow cytometry data in Figure 4b, both cell lines undergo time-dependent apoptotic process. It is found that the higher and faster apoptosis rate is shown in H460 cancer cells in comparison with L132 normal cells. The cell population at lower right part (Annexin V-PE-positive and 7-AAD-negative) representing the cells undergoing early apoptosis and upper right part (Annexin V-PE-positive and 7-AAD-positive) representing the cells undergoing late apoptosis of already dead cells have increased with time-dependent manner and it is shown to be much faster in H460.

Mitochondrial enzyme activity and ATP generation. In order to examine the distinctive nonthermal plasma effects

on mitochondria that has important roles in apoptosis, we measured MTS reduction and ATP generation in H460 and MRC5. MTS reduction is mainly attributed to mitochondrial enzymes and electron carriers,²⁰ which indicates the mitochondrial respiratory activity. Their final product ATP was quantified by luciferase in galactose-containing cell culture media.²¹ Galactose was used instead of glucose to exclude the ATP generation through glycolysis in cytoplasm in cancer cells.^{22,23} Interestingly, plasma induced significant changes in MTS reduction and ATP production with almost exactly same tendency (Figures 5a and b). Both relative values reduced more with plasma exposure time increase at day 1. The effect of 1-min-plasma exposure was almost negligible; however, longer plasma exposure (3 and 5 min exposure) induced significant reduction in mitochondrial enzyme activity as well as mitochondrial malfunction,

Figure 3 Fluorescence images of actin- (red) and mitochondria (green)-stained (a and b) H460 and (c and d) MRC5 cell lines. Actin staining shows the morphological changes of bumpy boundary in H460 and of wider adhesion in MRC5. Mitochondria become fragmented after 5 min plasma exposure in both cell lines. Scale bars are 10 μm

especially in H460. These reductions in mitochondrial respiration show similar tendency to the increase of Annexin V-positive apoptosis.

Mitochondrial membrane potential. MMP is known to be strongly related to mitochondrial potential. To determine MMP ($\Delta\psi_m$) change, we stained two cell lines with a lipophilic cationic dye JC-1, which aggregates in inner mitochondrial membrane to exhibit red fluorescence in normal polarized mitochondria and green fluorescence in depolarized mitochondrial membrane.¹¹ For positive MMP depolarization, we used a proton ionophore Carbonyl cyanide 3-chlorophenylhydrazone (cccp), which destroys the MMP quickly. Figure 6 is a graph of cell number distribution by green fluorescence intensity, representing mitochondrial membrane depolarization after plasma treatment in lung cancer cell H460 and lung normal cell MRC5. The green intensity increased (MMP decreases) following plasma exposure time in both cell lines; however, MMP of lung cancer cells decreased more to the level of MMP of cccp-treated positive cells. To quantify the relative change of MMP, we made the difference of green fluorescence intensity between negative control (0%) and cccp-treated positive control (100%), and the calculated relative intensity change was plotted in Figure 6c. The graph

shows >50% reduction in MMP (50% increase in JC-1 fluorescence) in H460 when they were treated with non-thermal DBD plasma for 1 min. Nonthermal plasma may be very effective to reduce MMP, because plasma treatment generates charged particles that can interrupt membrane polarity.

Moreover, we observed the mitochondrial ultrastructure change that is related to the MMP decreasing (Supplementary Figure S5, supporting information). In control cells, the mitochondrial ultrastructure showed various shape (elongate and circular) and size with clear cristae under transmission electron microscope observation.^{24,25} There happened significant damages on mitochondrial cristae in case of 5 min plasma-exposed H460, which may come from mitochondrial swelling, as shown in Figure 3. Structural change of mitochondrial cristae in MRC5 seemed little in TEM images, although they showed fragmentation in fluorescence microscope, as shown in Figure 3d.

Discussion

Selective killing of lung cancer cells by nonthermal plasma. Our study demonstrated that the nonthermal DBD plasma could induce high cell death in lung cancer cells.

Figure 4 The flow cytometry data of Annexin V and 7AAD staining of lung cells after plasma treatment. (a) The normalized cell number distribution to Annexin V intensity of H460 and MRC5 was plotted by plasma exposure time. H₂O₂ (1 mM) was used to make positive control. (b) Apoptosis of H460 and L132 cells was evaluated after 12 and 24 h incubation from nonthermal plasma treatment for 5 min. The number represents the percentage of cells in each quadruple

These phenomena can be understood by the generation of highly reactive radicals from the device. Plasma generated from atmospheric air contains radicals mainly from N₂ and O₂, which contains N, O, O₃, NO, NO₂, OH, and so on. The final products of these unstable species in liquid might be H₂O₂ and NO_x, which are quite stable. Although it is not clear what component of the nonthermal DBD plasma has a main role in these toxicity, we can point out that this dose-dependent toxicity have same tendency with the amount of H₂O₂ and NO_x melted in liquid as previous reports.²⁶ Direct generation of various kinds of ROS in culture media by nonthermal plasma has been known to increase intracellular ROS level linearly.^{6,27} Considering the strong cell line dependency in chemically induced endogenous ROS generation, this direct ROS generation can be generally good strategy in cancer therapy (A). Kalghatgi *et al.*⁶ Hoentsch *et al.*¹³ and Panngom *et al.*²⁸ reported that the cell culture media mediates the plasma effect on cell death and cell adhesion because of the interaction of plasma with organic components of cell culture media. The nonthermal DBD plasma might generate oxidative potential in cell culture media, which induced higher cell death in lung cancer cell lines than that in lung normal cell lines.

The main point in plasma cancer therapy should be the control of ROS dose for maximal cancer selectivity. In this

experiment, the survival rate of two lung cancer cells showed almost linear decrease following plasma exposure time. However, the survival rates of normal cells started to decrease after 1 min exposure. With higher plasma dose with longer time exposure, the survival rate of HCC1588 lung cancer cells was not significantly lower than L132 lung normal cells. This result implies that plasma power should be delicately controlled for selective cancer cell killing. Measuring the endogenous ROS level and antioxidant defense capacity might be necessary for decision.

Nonthermal plasma-induced apoptosis through mitochondrial damage. The cell death induced by nonthermal plasma was not necrotic but apoptotic. The population of Annexin V-stained cells and the population of PI-stained cells increased with increasing exposure time and incubation time, as shown in Figure 4. The percentage of apoptotic cells (H460) was 16% at 12 h and 48% at 24 h after 5 min plasma exposure. The percentage of late apoptosis also increased from 6 to 26% during 12h. Normal cells showed similar tendency with lower apoptotic ratio (28% in L132 and 15% in MRC5). This time-dependent cell death implies that the cell death induced by nonthermal plasma treatment was not necrotic. The apoptosis is a complex process that included at least two main processes consisting

Figure 5 DBD plasma effects on mitochondrial metabolic activity of H460 and MRC5 after 24 h from treatment. (a) The relative MTS value of H460 and MRC5, and (b) the relative ATP value of H460 and MRC5 in galactose media. H460 showed much decreased mitochondrial enzymatic activity with plasma exposure time in both assays. Students' *t*-test was performed to control (* denotes $P < 0.05$ and ** denotes $P < 0.01$)

of the extrinsic pathway and the intrinsic pathway.²⁹ Death receptors have a key role in mediating external signals to caspase8 in extrinsic pathway, and the mitochondria has a main role in deciding a cell fate in intrinsic pathway.³⁰ In our previous study, we showed upregulated mRNA expression of both *Caspase8* and *Bax* genes in H460 under plasma treatment, which implies the activation of both extrinsic and intrinsic pathways.¹³ Bax is a Bcl-2 family, which is related to signaling of mitochondrial membrane in the process of early apoptosis.²⁹

The nonthermal plasma-induced cell death may be strongly related to mitochondrial damages, especially in cancer cells. The nonthermal plasma reduced the mitochondrial enzyme activity and respiration rate, which significantly occurred in cancer cells with 3 and 5 min exposure. Moreover, it reduced the MMP significantly from 1 min exposure in cancer cells. The reduction of MMP is early prerequisite step toward apoptosis.^{11,31,32} The mitochondrial morphological change was also observed in 5 min plasma-treated cells, which is generally considered as unbalance between fission and fusion. There happened significant damages on mitochondrial cristae in the case of 5-min plasma exposure, which may come from mitochondrial swelling. According to the experiment of Gottlieb *et al.*³² mitochondrial swelling comes as a consequence of MMP decrease and permeability increase.³¹ This time-dependent differential phenomena in mitochondria may be understood as the sequence of events under ROS stress. MMP of cancer cells was reduced easily with small

Figure 6 The flow cytometry data of normalized cell number distribution in JC-1 green fluorescence intensity of (a) H460 and (b) MRC5 after plasma treatment. (c) The relative number value of JC-1 green fluorescence to control. The MMP of plasma-treated H460 decreased nearer to the cccp-treated value than MRC5 ($n=3$). Students' *t*-test was performed to control (* denotes $P < 0.05$ and ** denotes $P < 0.01$)

dose of ROS generated by nonthermal plasma, which might induce following events such as reduction in enzymatic activity, reduction in respiration rate, and unbalance in their morphological dynamics. In case of normal cells, however, the mitochondrial damage was not so severe with higher plasma dose. This differential mitochondrial response may be attributed to the higher respiration rate of cancer cells.²

On the basis of these mitochondrial severe damages, we can mention that targeting mitochondria is a good strategy in lung cancer therapy, and nonthermal DBD plasma treatment can be a good modality. According to previous reports, the mitochondrial targeting efficiency can be improved with drugs or genetic molecules.²¹ However, there should be delicate environmental control, because the mitochondrial enzyme activity was found to be very sensitive to nutritional supplements.^{33,34} Besides, the morphological abnormality of surviving normal cells after plasma treatment should be

considered, which is an important large-scale manifestation of the physiological state of cells.^{35–37} The physiological states of surviving normal cells and the underlying mechanisms should be studied to reduce unexpected side effects of plasma medicine.

In conclusion, we showed higher apoptotic cell death in lung cancer cell line H460 than that in lung normal cell lines MRC5 by the nonthermal DBD plasma treatment, in which mitochondrial dysfunction has an important role. The nonthermal DBD plasma treatment induced MMP decrease, mitochondrial enzymatic dysfunction, and mitochondrial morphological alteration in sequence. For therapeutic applications, the differential cellular responses to plasma treatment should be screened further according to cell morphology and cancer genotype. However, our results take the first step toward preferential killing of lung cancer cells by using the nonthermal DBD plasma treatment in lung cancer therapy.

Materials and Methods

Nonthermal DBD Plasma device. The DBD plasma consists of upper electrode made from silver and lower electrode made from stainless steel mesh. The device contained a 2.8-mm-thick upper glass and 1.8-mm-thick lower glass for dielectric substance, which was covered by stainless steel mesh. The diameter of DBD plasma area was about 80 mm. For AC power supply, commercial transformers for neon light operate at 60 Hz were used. The input voltage was about 80 V (breakdown voltage 600 V and breakdown electric current 0.01 A in r.m.s.) and the power was 5.7 W.

Cell culture and plasma treatment. Lung cancer cell lines (H460; human large-cell lung carcinoma cells and HCC1588; human squamous-cell lung carcinoma cells) and lung normal cell lines (MRC5; human fetal lung fibroblast cells and L132; human embryonic pulmonary epithelial cells) were purchased from Korean Cell Line Bank (Seoul, Korea). Cells were maintained in high glucose DMEM (SH30243.01, Hyclone, Logan, UT, USA) supplemented with 10% FBS (SH30979.03, Hyclone), 1% of penicillin/streptomycin (15140, Gibco, Grand Island, NY, USA) and cells were grown on incubator containing 5% of CO₂ at 37 °C. For plasma exposure, we used 5 ml of cell suspension with concentration of 1×10^5 cells/ml on the petridish (diameter ~9 cm, 10090, SPL, Pocheon-Si, Gyeonggi-do, Korea). The depth of media was about 0.8 mm, and we kept the distance between the plasma device and the bottom of petridish ~4 mm. After plasma exposure, cell suspension was divided into 96-well tissue culture test plate (30096, SPL; 1×10^3 cells per well) for cell number counting and mitochondrial enzyme activity. For flow cytometry analysis, cells were incubated on the cell culture dish (20100, SPL) for 24 h without dividing, and cells for image analysis were incubated on cover glasses for 24 h. Although both cell lines are adherent cells, plasma treatment in cell suspension state gives a little more stress than plasma treatment in adhesion state (Supplementary Figure S1, supporting information). Moreover, plasma exposure in both states induces similar time-dependent death rate.

Hydrogen peroxide (H₂O₂) and nitric oxide (NO_x) in media measurement. Amplex Red Hydrogen Peroxide Kit

(Molecular Probes, Invitrogen, Eugene, OR, USA) was used to measure the amount of H₂O₂ generated in media by DBD plasma. We added 50 μ l of standard curve samples, controls, and experimental samples to the 96-well plates with the 50- μ l Amplex Red reagent containing horseradish peroxidase solution. We incubated the plates for 30 min at room temperature in dark condition and detected fluorescence (ex.530/em.590) by fluorometer (Synergy HT, Biotek, Winooski, VT, USA).

NO_x was measured by using Nitric Oxide Colorimetric Assay kit (K262-200, Biovision, Milpitas, CA, USA). Nitrate reductase converted nitrate to nitrite, and Griess reaction was used to detect nitrate inside media. All steps of detection was performed according to the manufacturer's instructions. The absorbance was measured at 540 nm by spectrophotometer (Synergy HT, Biotek).

Cell number counting and mitochondrial metabolic activity assays.

Cells were harvested from 96-well plates at 24, 48, and 72 h from plasma treatment, and the cell number was counted by using hemocytometer under light microscope (Ti-U, Nikon, Tokyo, Japan). At the same time, the mitochondrial enzyme activity was measured by MTS (CellTiter 96 Aqueous Non-Radioactive Cell Proliferation Assay, Promega, Madison, WI, USA) assay. Fifty microlitres of MTS solution in DMEM (the ratio 1 : 5) was added into 96-well plate and the absorbance was measured at 490 nm after 2 h incubation by using spectrophotometer (Synergy HT, Biotek). The amount of ATP generated in both cell lines was measured at 24 h from plasma treatment. Cells were harvested, and same number of cells (2×10^3 cells per well) were seeded in white-walled 96-well assay plate (3610, Corning Inc, Corning, NY, USA). Following the manufacturer's instruction of Mitochondrial ToxGlo Assay (Promega), the amount of ATP was measured by luminescence using a plate reader (Synergy HT, Biotek). cccp (0.05 mM) was used for positive control.

Cellular and mitochondrial morphology. Actin fibers and mitochondria were stained after 24 h of plasma treatment. Cells on cover glass were washed with DPBS (WelGene, Daegu, Korea), fixed with 4% (v/v) paraformaldehyde (15713, Electron Microscopy Sciences, Hatfield, PA, USA) for 15 min, and permeabilized by 0.1% (v/v) Triton X-100 (T8532, Sigma, St. Louis, MO, USA) in PBS for 20 min at room temperature. After washing with PBS three times, actin fibers were stained by phalloidin dye (5 units/ml, Phallotoxins, Invitrogen) for 30 min at room temperature. After washing with PBS three times, mitochondria were stained by MitoTracker dye solution (200 nM, MitoTracker Mitochondrion-Selective Probes, Invitrogen). Samples were mounted with 50% (v/v) glycerol and observed under $\times 40$ magnification of light and fluorescence microscope (Ti-U, Nikon).

Apoptosis detection. EzWay Annexin V-FITC apoptosis detection kit (Komabiotek, Inc, Seoul, Korea) was used for apoptotic analysis. After 24 h incubation, cells were trypsinized, washed with 0.5 ml of cold DPBS, and suspended with 0.5 ml by cold $1 \times$ binding buffer. Then, 1.25 μ l of Annexin V-FITC (0.5 μ g/ml) were added and incubated for 15 min at room temperature in the dark condition. Cells were

washed and stained with 10 μ l PI (0.3 μ g/ μ l) or 5 μ l 7-AAD (51-68981E, BD Biosciences, San Jose, CA, USA), and observed by fluorescent microscopy (Ti-U, Nikon) and flow cytometry (BD FACSVerse, BD Biosciences).

MMP ($\Delta\psi_m$) analysis. MMP of cells were detected by using MitoProbe JC-1 assay kit for flow cytometry (M34152, Molecular Probes) after 24 h incubation. Cells were resuspended in 1 ml media containing of JC-1 dye (2 μ M), and incubated at 37 °C, 5% CO₂ for 40 min. After washing with 500 μ l of PBS, the samples were analyzed by using flow cytometry. Before harvesting cells, we added 1 μ l of 50 mM cccp, and incubated for 10 min at 37 °C for a positive control.

Statistical analysis. All values are represented by the mean $\pm$ S.D. of the indicated number of replicates. Statistical analyses of the data were performed using student's *t*-test to establish significance between data points, and significant differences have been based on the $P < 0.05$ or $P < 0.01$.
