HMGB1 release by H₂O₂-induced hepatocytes is regulated through calcium overload and 58-F interferencePei Zhao¹, Tingjie Ye², Xiaofeng Yan², Xudong Hu², Ping Liu^{3,4} and Xiaoling Wang²

HMGB1 is passively released by injured or dying cells and aggravates inflammatory processes. The release of HMGB1 and calcium overload have each been reported to be important mediators of H₂O₂-induced injury. However, a potential connection between these two processes remains to be elucidated. In the present study, we employed H₂O₂-induced hepatocytes to investigate how calcium overload takes place during cellular injury and how the extracellular release of HMGB1 is regulated by this overload. In addition, we investigated the use of 58-F, a flavanone extracted from *Ophiopogon japonicus*, as a potential therapeutic drug. We show that the PLC γ 1–IP₃R–SOC signalling pathway participates in the H₂O₂-induced disturbance of calcium homeostasis and leads to calcium overload in hepatocytes. After a rise in intracellular calcium, two calcium-dependent enzymes, PKC α and CaMKIV, are activated and translocated from the cytoplasm to the nucleus to modify HMGB1 phosphorylation. In turn, this promotes HMGB1 translocation from the nucleus to the cytoplasm and subsequent extracellular release. 58-F effectively rescued the hepatocytes by suppressing the PLC γ 1–IP₃R–SOC signalling pathway and decreasing the calcium concentration in cells, thus reducing HMGB1 release.

INTRODUCTION

Calcium is a universal second messenger involved in a remarkably wide range of cellular processes.¹ Disordered cytosolic calcium signalling can lead to severe damage or result in cell death.^{2,3} In non-excitable cells, Ca²⁺ signals are generated by the phospholipase C (PLC)-mediated hydrolysis of phosphatidylinositol bisphosphate (PIP₂) to yield 1,4,5- trisphosphate (IP₃), leading to the subsequent activation of the inositol trisphosphate receptor (IP₃R). This mediates the release of Ca²⁺ from the endoplasmic reticulum (ER),⁴ followed by transmembrane Ca²⁺ entry through the opening of store-operated calcium (SOC) channels.⁵ SOC channels are the predominant mechanism of calcium entry in both excitable and non-excitable cells and are activated by the depletion of internal calcium stores, for example, from the ER. Upon opening, SOC channels promote calcium entry through the plasma membrane (PM), a major mechanism for Ca²⁺ influx.^{6,7} So far, two major molecular components of the SOC channel signalling pathway have been identified: stromal interaction molecule 1 (STIM1) and Orai1.^{8,9} STIM1 serves as a calcium sensor that can directly bridge the ER to PM at specialized junctions, aggregating into puncta in response to calcium store depletion and triggering the activation of SOC channels located in the PM.¹⁰ Orai1 channels comprise six monomers and are localized diffusely in the PM of resting cells. They are recruited into puncta by STIM1 through a direct interaction, opening SOC channels to mediate store-operated calcium entry (SOCE) to ensure the optimal refilling of the ER.^{11,12} SOCE plays a major role in Ca²⁺ influx in non-excitable cells, including hepatocytes.¹³ Patch-clamp experiments in liver cells showed that only one type of SOC channel, a highly

Ca²⁺-selective channel, could be detected.^{14,15} Therefore, SOC channels are a research hotspot in the physiology and pathology of liver disease.

Hydrogen peroxide (H₂O₂) is a key mediator underlying cellular oxidative stress and is involved in a wide variety of pathological processes. It can cause intracellular Ca²⁺ overload in various cell types due to oxidative stress.^{16–18} Therefore, any therapeutic approach that can prevent H₂O₂-induced intracellular Ca²⁺ overload and improve intracellular Ca²⁺ regulation would be beneficial for cells. On the other hand, PLC γ 1, the first protein in the PLC γ 1–IP₃R–SOC Ca²⁺ signalling pathway, is upregulated as a result of H₂O₂-induced oxidative stress. PLC isozymes are subdivided into three types (β , γ , δ), and the γ type includes two isoforms (PLC γ 1 and PLC γ 2). While PLC γ 1 shows a ubiquitous expression pattern, PLC γ 2 is mainly expressed in B-cells.¹⁹ Moreover, it is well established that PLC γ 1 undergoes direct phosphorylation on tyrosine residues in response to H₂O₂ treatment.^{20,21} However, to the best of our knowledge, whether PLC γ is involved in H₂O₂-induced Ca²⁺ release in hepatocytes remains unknown.

High mobility group box 1 (HMGB1) is a highly conserved 30 kDa DNA-binding protein. In response to injury, HMGB1 is passively released from stressed cells,²² and excessive extracellular HMGB1 adversely contributes to injury-elicited pathogenesis.²³ In the same way, HMGB1 plays a key role in various forms of liver injury.²⁴ The release of HMGB1 is controlled by two critical steps that regulate the flux of HMGB1 from the nucleus to the cytoplasm and subsequently from the cytoplasm to the extracellular compartment. The phosphorylation of HMGB1 at critical serine

residues is essential for its translocation from the nucleus to cytoplasm.²⁵ The activation of two calcium-mediated protein kinases, classical protein kinase C (PKC) and Ca²⁺/calmodulin-dependent protein kinase IV (CaMKIV), is required for HMGB1 phosphorylation.^{26,27} PKC has many isoenzymes, and among them, PKC α is involved in HMGB1 release.²⁶ CaMKs are a family of proteins comprising CaMK I–IV. Activation typically requires Ca²⁺/calmodulin binding and can be augmented or sustained by phosphorylation. The identity of the specific CaMK family members involved in hypoxia-induced HMGB1 release is uncertain, but H₂O₂ treatment has been shown to activate CaMKIV in hepatocytes.²⁸ In the present report, we employed these two calcium-dependent enzymes to determine whether they participate in HMGB1 phosphorylation associated with secretion.

Oxidative stress sensitizes hepatocytes to either calcium overload²⁹ or HMGB1 release.³⁰ Although HMGB1 and calcium have been separately reported to be important mediators of oxidative stress-induced injury, the potential relationship between them remains unknown. Here, we evaluate the hypothesis that SOCE activation causes calcium influx leading to calcium overload after H₂O₂ treatment, followed by the activation of PKC α and CaMKIV and HMGB1 release in hepatocytes. Our findings support this hypothesis, demonstrating that SOCE activation leads to a cytosolic calcium increase and HMGB1 release from cells after H₂O₂ treatment. In addition, the compound 5,8-dimethoxy-6-methyl-7-hydroxy-3-(2-hydroxy-4-methoxybenzyl) chroman-4-one (58-F) is a flavanone extracted from *Ophiopogon japonicus*, which has been widely distributed and used clinically in mainland China,^{29,31} and we recently reported that 58-F protects against ROS-induced liver injury.³² In the present study, we explore the protective contribution of 58-F to H₂O₂-induced calcium homeostasis and HMGB1 release.

RESULTS

Release of HMGB1 following H₂O₂-induced hepatocyte injury/death is involved in calcium entry

Our previous studies found that H₂O₂ could induce apoptosis by disrupting cellular calcium homeostasis.³³ To confirm the effect of H₂O₂ on cell injury/death, we examined the release of lactate dehydrogenase (LDH) from cells to media as well as the levels of HMGB1 in the media, cytosol and nucleus. After incubation with 500 μ M H₂O₂ for varying times, the levels of LDH in the cellular media increased approximately 2.5 and 3-fold at 8 and 12 h, respectively (Figure 1a). HMGB1 is passively released to the extracellular space upon cellular injury/death by almost all cells that have a nucleus, and it acts as a signal to neighbouring cells of ongoing damage.²³ Moreover, 500 μ M H₂O₂ led to an increase in HMGB1 release into the media (Figure 1b), and western blot analysis of cytosolic and nuclear lysates revealed that the amount of HMGB1 protein progressively increased in the cytosol and decreased in the nucleus after H₂O₂ treatment (Figures 1c and d). Pretreatment with 100 μ g/ml *N*-acetylcysteine (NAC), a common antioxidant, decreased the content of HMGB1 in the media (Figure 1b). However, HMGB1 levels in the cytosol and nucleus continued to trend the same way with or without the antioxidant (Figures 1e and f). Further, we tested the effects of calcium signalling pathway inhibitors on HMGB1 release. HMGB1 levels in the cellular media induced by H₂O₂ exposure were markedly reduced by pretreatment with 10 μ M U73122 (a PLC inhibitor) or 50 μ M 2-APB (an IP₃R inhibitor) (Figure 1b). These findings indicate that cellular injury or death caused by H₂O₂ leads to the release of HMGB1 and that this process is regulated by a calcium signalling pathway.

PLC γ 1–IP₃R–SOC participate in H₂O₂-induced calcium entry into cells

To determine whether H₂O₂ affects calcium signalling in hepatocytes through SOC channels, we performed calcium imaging of hepatocytes stimulated with 500 μ M and 1 mM H₂O₂ in a calcium-free buffer (plus 1 mM EGTA). We observed an increase in the height of the left peaks representing Ca²⁺ transients in the cytoplasm, due to calcium release from intracellular store(s) for example, from the ER (Figure 2a). After replacing the extracellular medium with a 2 mM calcium chloride solution, an increase in the heights of the right peaks representing Ca²⁺ transients in the cytoplasm from media were observed (Figure 2a), indicating extracellular calcium influx through the PM due to the depletion of ER stores. Furthermore, NAC was used to assess whether the calcium influx was caused by oxidative stress, and we observed a significant reduction of H₂O₂-induced left and right peaks after NAC pretreatment (Figures 2c and d).

To investigate the possible involvement of PLC in H₂O₂-induced cytosolic calcium increases, cells were pre-treated with 10 μ M U73122 before H₂O₂ addition. The two peaks representing calcium entry into the cytoplasm were significantly reduced when cells were pre-treated with U73122 before H₂O₂ addition, revealing that PLC contributes to the cytosolic calcium increase. PLC is known to stimulate IP₃R in the ER membrane through the synthesis of IP₃. Thus, to determine whether this pathway is important for H₂O₂-induced calcium increase, cells were pre-incubated with 50 μ M 2-APB (an IP₃R inhibitor), which also led to significantly reduced H₂O₂-induced cytosolic calcium (Figures 2e and f). In addition, we assessed the role of SOC channels in this calcium influx by knocking down STIM1 with shRNA (Figures 2i and j). si-STIM1 inhibited the elevation of the right peak but not the left peak of calcium influx, indicating that SOC channels affect extracellular calcium influx without altering ER Ca²⁺ store release (Figures 2g and h). Together, these results support the notion that PLC induces a signalling cascade through IP₃ and the subsequent stimulation of SOC channels to mediate H₂O₂-induced cytosol calcium increase.

To further validate proteomic changes that might be responsible for the H₂O₂-induced cytosolic calcium increase, the levels of some related proteins were assessed via western blot. Cells were exposed to H₂O₂ at concentrations of 100, 500 or 1000 μ M for 4 h or 500 μ M for 1, 2, 3 or 4 h. The results revealed that both STIM1 and Orai1 protein levels increased in a H₂O₂ concentration- and time-dependent manner (Figures 3a–d). Furthermore, NAC and 2-APB reversed this H₂O₂-induced increase in STIM1 and Orai1 levels (Figures 3e–h).

Because the PLC–IP₃R pathway triggers SOC channels, we tested the levels of phosphorylated and total PLC γ 1 after H₂O₂ treatment. Our results showed that H₂O₂ did not stimulate an increase in total PLC γ 1 protein, but the levels of phosphorylated protein increased. These changes were significantly attenuated by the PLC γ 1 inhibitor U73122 (Figures 3i and j).

HMGB1 secretion and translocation are Ca²⁺ dependent

To determine whether intracellular calcium overload could induce cell injury, cells were treated with different concentrations (10, 25 and 50 μ M) of A23187, a calcium ionophore and intracellular Ca²⁺ levels were examined using Fluo-4/AM. Intracellular fluorescence signals gradually increased from 10 to 50 μ M in a concentration-dependent manner with A23187 treatment (Figures 4a and b). However, the bright fluorescence signals induced by A23187 were dampened by co-treatment with 1 mM EGTA, a calcium chelator. We also measured the release of LDH into the media under these conditions by ELISA assay (Figures 4c and d) and observed a significant concentration- and time-dependent increase with the A23187 treatment (Figures 4c and d). These results indicate that intracellular calcium overload induces cellular injury.

Figure 1. HMGB1 release induced by H₂O₂ is calcium dependent. **(a)** The rate of cell injury was measured using a Cytotoxicity LDH Assay Kit. **(b)** The cells were pre-treated with 100 μ g/ml NAC, 50 μ M 2-APB or 10 μ M U73122 for 16 h, then co-incubated with H₂O₂ for 8 h, and HMGB1 levels in media were measured by ELISA. **(c and d)** The cells were treated with 500 μ M H₂O₂, and a western blot was used to measure HMGB1 protein levels in the cytosolic/nuclear fractions at 4, 6, 8 and 12 h. **(e and f)** The cells were pre-treated with NAC for 16 h, then co-incubated with H₂O₂ for 8 h and HMGB1 levels in the cytosolic/nuclear were measured by western blot. Shown are representative results from one of three independent experiments. * P < 0.05, ** P < 0.01, *** P < 0.001, compared with the control; # P < 0.05, ### P < 0.001, compared with the H₂O₂ treatment group.

Similarly, HMGB1 levels in the cellular media increased with increasing concentrations of A23187 treatment (10, 25 or 50 μ M) in a concentration-dependent manner and also markedly increased at 24 and 48 h in a time-dependent manner (Figures 5a and b). Under the same conditions, the HMGB1 levels in the nucleus gradually decreased after A23187 treatment (10, 25 or 50 μ M), consistent with a corresponding increase in cytosolic levels (Figures 5c and d). Similar results were observed with different time periods of A23187 incubation (Figures 5e and f). Furthermore, in cells treated with 25 μ M A23187 combined with 1 mM EGTA, HMGB1 levels in the media and cytosol significantly decreased, coincident with an increase in nuclear levels (Figures 5g–i). Together,

these results indicate that A23187 induces HMGB1 translocation and release through an increase in intracellular calcium.

It is reported that PKC α and CaMKIV are involved in HMGB1 phosphorylation and release.^{26,34} To elucidate whether HMGB1 release from hepatocytes under oxidative stress is also dependent on these kinases, we examined changes in nuclear PKC α and CaMKIV levels and their interaction with HMGB1 after H₂O₂ exposure. The content of PKC α in the nucleus after H₂O₂ treatment increased at approximately 4–5 h, then decreased from 6 h. CaMKIV content increased at approximately 5–6 h and went down at 8 h (Figures 6a and b). The results of immunoprecipitation analysis of HMGB1 with PKC α or CaMKIV showed that both PKC α

Figure 3. SOC participates in the H₂O₂-induced disturbance of calcium homeostasis. (a–h) Western blot for STIM1 and Orai1 protein. Cells were stimulated with H₂O₂ at varying concentrations (100 μ M, 500 μ M or 1 mM) for 4 h (a and b) or were stimulated for varying periods of time (1, 2, 3 or 4 h) with 500 μ M H₂O₂ (c and d). Cells were pre-treated with 100 μ g/ml NAC (e and f) or 50 μ M 2-APB (g and h) or 10 μ M U73122 (i and j) for 21 h, then co-incubated with 500 μ M H₂O₂ for 3 h. PLC γ 1 and p-PLC γ 1 were detected by western blot. Shown are representative results from one of three independent experiments. * P < 0.05, ** P < 0.01, *** P < 0.001, compared with the control; # P < 0.05, ## P < 0.01, compared with the H₂O₂-treated group.

and CaMKIV can directly interact with HMGB1 in the nucleus over different time periods (Figure 6c).

Owing to the calcium-dependence of PKC α and CaMKIV activity, we also measured the role of A23187 in the interactions of PKC α and CaMKIV with HMGB1. The results showed that the nuclear levels of PKC α increased at 0.5 and 1 h but decreased at 2–3 h after A23187 treatment. Additionally, the levels of CaMKIV increased at 0.5–2 h and went down at 3 h after A23187 treatment. This indicates that both kinases are induced by

A23187 treatment but that CaMKIV induction persists longer than PKC α induction (Figures 6d and e). To observe whether the interactions of PKC α or CaMKIV with HMGB1 in the nucleus are also regulated by calcium, nuclear extracts isolated from cells treated with or without A23187 were immunoprecipitated with anti-HMGB1. Both PKC α and CaMKIV could be observed in the resulting western blot (Figure 6f). These results suggest that PKC α and CaMKIV directly bind to HMGB1 in A23187-treated cells.

Figure 4. A23187-induced cell injury. **(a and b)** Intracellular Ca²⁺ levels at 24 h after A23187 treatment (10, 25, 50 μM) or in the presence of 1 mM EGTA plus A23187 treatment (25 μM, 50 μM) visualized by confocal microscopy. **(c and d)** The rate of cell injury assessed using the Cytotoxicity LDH Assay Kit. Shown are representative results from one of three independent experiments. **P* < 0.05, ***P* < 0.01, ****P* < 0.001, compared with the control; [#]*P* < 0.05, compared with the 25 μM A23187-treated group; &&*P* < 0.01, compared with the 50 μM A23187-treated group.

Effects of 58-F on the PLCγ1–IP₃R–SOC signalling pathway in the H₂O₂-induced [Ca²⁺]_i increase

Recently, we reported that 58-F protects against ROS-induced liver injury. In addition, we also showed that H₂O₂ could induce apoptosis by disrupting cellular calcium homeostasis.^{33,35} The [Ca²⁺]_i increase by H₂O₂ prompted us to investigate the possibility that the inhibition of Ca²⁺ influx by 58-F is at least partly due to the suppression of the PLCγ1–IP₃R–SOC signalling pathway. The level of calcium entry into cells with or without 58-F pretreatment was detected by calcium imaging and confocal microscopy. In agreement with Figure 2, the stimulation of hepatocytes with 500 μM H₂O₂ in a calcium-free buffer led to an increase in cytosolic calcium due to the release of calcium from ER stores. After replacing the extracellular medium with a 2 mM CaCl₂ solution, a further increase in cytosolic calcium through the PM was apparent, due to the depletion of ER stores. Notably, the fluorescence intensity after adding H₂O₂ and CaCl₂ was attenuated by pretreatment with 50 or 100 μM 58-F (Figures 7a and b).

To assess the effects of 58-F on the protein levels of members of the PLCγ1–IP₃R–SOC signalling pathway, we measured the levels of STIM1, Orai1, PLCγ1 and p-PLCγ1 following treatment. The H₂O₂-induced increased levels of both STIM1 and Orai1 were reduced by pretreatment with 58-F at concentrations ranging from 10 to 100 μM or by pretreatment with 50 μM 58-F for different periods of time (24, 48 or 72 h) (Figures 7c–f). Furthermore, similar to the effects observed with U73122, 58-F significantly attenuated the increased levels of p-PLCγ1 induced by H₂O₂ without affecting the levels of total PLCγ1 (Figures 7g and h). These findings suggest that 58-F suppresses the H₂O₂-induced [Ca²⁺]_i increase through PLCγ1-mediated SOC channels.

Effects of 58-F on the translocation and release of HMGB1 induced by H₂O₂

To confirm the cellular protective effect of 58-F, we examined the release of LDH from cells to media and the levels of HMGB1 in the media, cytosol and nucleus. The extracellular release of both LDH

and HMGB1 was decreased after pretreatment with 10, 50 or 100 μ M 58-F (Figures 8a and b). Additionally, the translocation of HMGB1 from the nucleus to the cytosol was also suppressed in time- and dose-dependent manners (Figures 8c–f).

Likewise, the nuclear levels of PKC α and CaMKIV in cells pretreated with 50 μ M 58-F were significantly less than those in cells with a single H₂O₂ treatment from 4 to 5 h (Figures 8g and h). To further assess the direct interaction of PKC α or CaMKIV with HMGB1,

Figure 5. A23187-induced HMGB1 translocation and release in hepatocytes. **(a and b)** HMGB1 contents in culture media were determined using ELISA. **(c–f)** HMGB1 protein levels in cytosolic/nuclear fractions were measured by western blot. nuclear lysates were immunoprecipitated with anti-HMGB1, then subjected to western blot with PKCα or CaMKIV antibodies. The direct interaction of PKCα and CaMKIV with HMGB1 in the nucleus was inhibited by 58-F pretreatment (Figure 8i).

DISCUSSION

A PLCγ1–IP₃R–SOC signalling pathway is involved in the disturbance of calcium homeostasis in hepatocytes induced by H₂O₂.

Calcium signals, which can be induced by a variety of stimuli, control a myriad of functions in cells. Hepatocytes can increase their cytoplasmic Ca²⁺ concentration in two ways: release from intracellular storage pools, primarily ER,³⁶ and the entry of extracellular calcium to maintain adequate Ca²⁺ stores. It is well established that PLCγ1 undergoes phosphorylation on tyrosine residues in response to H₂O₂ treatment.^{20,21} Under either physiological or pathological conditions, the activation of the PLCγ1 pathway produces IP₃, which binds to its receptor IP₃R in the ER and mobilizes Ca²⁺ out of ER. Subsequently, SOC channels are activated, leading to Ca²⁺ influx and the replenishing of ER stores. In our study, the role of PLCγ1–IP₃R signalling in SOC was examined, and the results showed that H₂O₂-induced elevated [Ca²⁺]_i was almost abolished and that the increased phosphorylation of PLCγ1 was reduced when cells were pre-treated with the generic PLC inhibitor U73122 or the IP₃R inhibitor 2-APB. These findings are in agreement with earlier publications reporting that the phosphorylation and activation of PLC by a sulfhydryl oxidation-dependent mechanism, which leads to increased IP₃ synthesis and subsequent activation of the IP₃ receptor, induces the release of Ca²⁺ from intracellular stores^{37,38} and that the

H₂O₂-induced [Ca²⁺]_i rise could be prevented by U73122 or 2-APB.³⁹ SOC is defined as enhanced Ca²⁺ import from the extracellular space after depletion of calcium in the ER.^{6,40} Among all Ca²⁺-permeable channels confirmed to be expressed in hepatocytes, SOC channels are the principal pathway for Ca²⁺ influx through the PM.^{35,41} To confirm whether SOC participates in H₂O₂-induced Ca²⁺ influx, we carried out a series of experiments. First, our data demonstrate that H₂O₂ elicits an increase in intracellular [Ca²⁺]_i in the absence of extracellular calcium, indicating that H₂O₂ can mobilize calcium out of the ER. After adding CaCl₂, an apparent extracellular Ca²⁺ influx was observed, and the overall rise in calcium concentration significantly increased. Furthermore, the antioxidant NAC inhibited Ca²⁺ influx from the extracellular space. These findings are in agreement with the view that H₂O₂ triggers Ca²⁺ release into the cytoplasm in two steps: Ca²⁺ release from internal stores, followed by SOC from the extracellular supply. Second, the protein levels of STIM1 and Orai1 increased after H₂O₂ treatment, while si-STIM1 almost abolished the H₂O₂-induced Ca²⁺ influx without affecting the release of Ca²⁺ from the ER (Figure 2). Moreover, NAC was found to inhibit the H₂O₂-induced increase of STIM1 and Orai1 protein levels. These findings confirm that Ca²⁺ enters cells through activated SOC channels with H₂O₂ stimulation. Together, we conclude that calcium overload in hepatocytes caused by H₂O₂ occurs through the PLCγ1–IP₃R–SOC signalling pathway.

The increase of intracellular calcium can activate PKCα and CaMKIV to promote HMGB1 release.

Extracellular HMGB1 is derived from either active secretion by innate immune cells or by passive release from dead or stressed cells as a late inflammatory mediator for infectious or

Cells were pre-treated with 50 μM 58-F for 20 or 19 h, then co-incubated with 500 μM H₂O₂ for 4 or 5 h. Nuclear extracts were harvested, immunoprecipitated with anti-HMGB1 and protein A agarose, then subjected to western blot analysis for PKCα and CaMKIV. Shown are representative results from one of three independent experiments. **P* < 0.05, ***P* < 0.01, ****P* < 0.001, compared with the control; #*P* < 0.05, ##*P* < 0.01, ###*P* < 0.001, compared with the H₂O₂-treated group; △*P* < 0.05, compared with the H₂O₂-treated 4 h group; &&*P* < 0.01, compared with the H₂O₂-treated 5 h group.

noninfectious inflammation.²⁴ The passive release of HMGB1 from dead/stressed cells is due to its export from the nucleus to the cytoplasm and subsequent release into the extracellular space due to increased cell membrane permeability.^{23,42} Youn and co-workers⁴³ and Tsung Allan *et al.*²⁸ have reported that HMGB1 release can be induced by A23187 in murine hepatocytes or in RAW264.7 cells and that this release is reduced by BAPTA, a chelator of Ca²⁺, indicating that Ca²⁺ plays a critical role in oxidative stress-induced HMGB1 release. Our results show that

both HMGB1 and LDH contents in the media increased after H₂O₂ treatment and that HMGB1 levels in the media induced by H₂O₂ exposure are markedly reduced by pretreatment with either the antioxidant NAC or the calcium pathway inhibitors 2-APB or U73122. This confirms the finding that HMGB1 release from stressed/dead cells due to oxidative stress is regulated by calcium homeostasis. To further verify the possibility that Ca²⁺ overload in the cytosol due to oxidative stress leads to HMGB1 release, we employed the calcium ionophore A23187.

Our data show that increasing intracellular levels of calcium with A23187 results in the translocation of HMGB1 from the nucleus to the cytosol and its release to the extracellular space, which was markedly reduced by treatment with the calcium chelator EGTA.

Phosphorylation of serine residues within the HMGB1 nuclear localization signal may also contribute to the regulation of HMGB1 cytoplasmic translocation, which is a key step for its release into the extracellular space.^{22,25} Two calcium-dependent kinases, CaMKIV and PKC α , have been implicated in the regulation of HMGB1 phosphorylation and release.^{27,43} Signalling events upstream of PKC α and CaMKIV include Ca²⁺ release from the ER. We noted an increase in the levels of both PKC α and CaMKIV within the nucleus and an enhancement of their direct interaction with HMGB1 after A23187 stimulation. This is consistent with the results of H₂O₂ treatment, supporting the view that the H₂O₂-mediated increase in cytoplasmic Ca²⁺ is sufficient to activate CaMKIV and PKC α nuclear translocation and HMGB1 phosphorylation.

58-F intervention regulates intracellular calcium and reduces the release of HMGB1 induced by H₂O₂

Accumulating evidence directly implicates HMGB1 in various diseases, and it has been considered as a therapeutic target for sterile inflammation and infection.⁴⁴ We recently reported that 58-F protected against ROS-induced liver injury, but the mechanism was still to be elicited. The results reported in this work indicate that 58-F inhibits calcium entry through SOC channels triggered by the PLC γ 1-IP₃R signalling pathway in response to oxidative damage. We also showed that 58-F suppresses HMGB1 translocation from the nucleus to the cytoplasm and its eventual extracellular release by inhibiting the activation of PKC α and CaMKIV.

CONCLUSION

In summary (Figure 9), we determined the role of the PLC γ 1-IP₃R-SOC signalling pathway in the regulation of calcium influx in cells undergoing oxidative stress and identified calcium homeostasis in hepatocytes as a key mechanism regulating HMGB1 translocation from the nucleus to the cytoplasm for extracellular release. Our data further support the idea that calcium-dependent kinases PKC α and CaMKIV participate in HMGB1 phosphorylation, a key step leading to HMGB1 release. On the basis of these findings, 58-F, a flavanone extracted from *O. japonicus*, was shown to interfere with calcium overload caused by the response of the PLC γ 1-IP₃R-SOC signalling pathway to oxidative stress and with the PKC α - and CaMKIV-mediated regulation of HMGB1 release. These findings may be important for designing therapies to prevent hepatocytes from oxidative stress-induced injury/death.

MATERIALS AND METHODS

Drugs and reagents

Thirty percent H₂O₂ was purchased from Sinopharm Chemical Reagent Co. (Shanghai, China). 58-F was purchased from Shanghai Yilin Biotechnology Co., Ltd (Shanghai, China). A23187 was purchased from Abcam (Cambridge, MA, USA). 2-Aminoethoxydiphenyl borate(2-APB) and NAC were purchased from Sigma (St. Louis, MO, USA). EGTA was purchased from Amresco (Solon, OH, USA). U73122 was purchased from Selleck (Houston, TX, USA). Dulbecco's modified Eagle's medium (DMEM), fetal calf serum (FBS) and penicillin-streptomycin were purchased from Gibco (Carlsbad, CA, USA). Hanks and D-Hanks were purchased from Gino Biological Pharmaceutical Co., Ltd (Hangzhou, China). Fluo-4/AM, Pluronic F-127 and Cytotoxicity LDH Assay Kit were purchased from Dojindo (Kumamoto, Japan). Rabbit anti-rat antibodies against STIM1, PLC γ 1, p-PLC γ 1, GAPDH, β -actin were purchased from Santa Cruz Biotechnology (Dallas, TX, USA); Orai1, HMGB1, PKC α , CaMKIV, Histone H3 were purchased from Abcam. Goat anti-rabbit horseradish peroxidase-conjugated secondary antibody was purchased from Shanghai Excell Biotechnology Co., Ltd (Shanghai, China). The BCA

Figure 9. HMGB1 release regulated by the PLC γ 1-IP₃R-SOC signalling pathway during calcium overload in hepatocytes. The proposed model showing the release of HMGB1 following H₂O₂ treatment. H₂O₂ activates the PLC γ 1-IP₃R-SOC signalling pathway, leading to calcium influx and the activation of calcium-dependent kinases PKC α and CAMKIV and triggering HMGB1 phosphorylation. Phosphorylated HMGB1 translocates from the nucleus to the cytoplasm and is ultimately released into the extracellular space.

protein assay kit, SDS-PAGE and Protein A agarose were purchased from (Shanghai, China). Enhanced chemiluminescence detection system was purchased from Millipore (Billerica, MA, USA). The HMGB1 enzyme-linked immunosorbent assay (ELISA) kit was purchased from Chondrex (Redmond, WA, USA). Nuclear and cytoplasmic extraction reagents was purchased from Shanghai Yisheng Biotechnology Co., Ltd (Shanghai, China).

Cellular culture and treatment

BNL-Cl₂ cells were cultured in DMEM medium supplemented with 10% FBS, 1% penicillin and streptomycin at 37°C with 5% CO₂, and the culture media were changed once every 2 days. At 80–90% confluence, cells were treated with various agents in medium with 2% FBS. For H₂O₂ treatment, cells were incubated with 100 μM, 500 μM or 1 mM H₂O₂ for 1, 2, 3 or 4 h. For NAC treatment, cells were pre-treated with 100 μg/ml NAC for 24 h. For inhibition experiments, the cells were pre-treated with 50 μM 2-APB or 10 μM U73122 for 24 h and then co-treated with 500 μM H₂O₂ for 3 h. For RNAi experiments, cells were transfected with NC-siRNA or STIM1-siRNA. For A23187 treatment, cells were treated with 10, 25 or 50 μM A23187 for 30 min; then, the medium was replaced with new DMEM with 2% FBS for 12, 24 or 48 h. Cells were co-treated with 25 μM A23187 and EGTA (25 μM) for 30 min. For 58-F administration, the cells were pre-treated with 58-F at 10, 50 or 100 μM for 24, 48 or 72 h and then exposed to 500 μM H₂O₂ for 3 h.

Measurement of intracellular Ca²⁺ concentration

Intracellular Ca²⁺ was monitored using the Ca²⁺-sensitive fluorescent indicator-Fluo-4/AM by confocal laser scanning microscopy. The cells were cultured in confocal dishes (10⁵ cells/dish), then loaded with Fluo-4/AM (5 μM) and F127 (0.4%) at 37 °C for 30 min in darkness with modified Hank's Buffered Salt Solution (HBSS) containing 25 mM Hepes, 150 mM NaCl, 5 mM KCl, 2 mM CaCl₂, 0.4 mM MgCl₂ and 25 mM D-glucose (pH 7.4). They were rinsed twice in HBSS and kept at room temperature for 10 min to allow the de-esterification of Fluo-4/AM. Then, cells were maintained in D-Hanks (Ca²⁺-free) buffer for 10 min before Ca²⁺ imaging. The green fluorescence of Fluo-4/AM was excited by an argon laser at 488 nm, and the emitted fluorescence was recorded through a 525 nm channel. The image was recorded every 10 s. For imaging with Fluo-4/AM, [Ca²⁺]_i changes are presented as F/F₀ ratios after background subtraction, where F was the change in fluorescence signal intensity, and F₀ was the baseline before stimulus application.

LDH cytotoxicity assay

LDH release, which could reflect cell membrane integrity, was detected with an assay kit (Dojindo) according to the manufacturer's instructions. Briefly, cells were cultured in 96-well microplates (7 × 10³ cells/well) for 24 h in a CO₂ incubator and then incubated with different treatments. First, 10 μl of Lysis Buffer was added to the well to induce maximum LDH release. After 30 min in a CO₂ incubator, 100 μl of Working Solution was added into each well, and the plates were incubated in darkness at room temperature for 30 min. Subsequently, 50 μl of Stop Solution was added to each well, and the absorbance was measured at 490 nm using a microplate reader. The calculation was as follows: LDH release (%) = [A - C/B - C] × 100%, where A is the absorbance of treated samples, and B and C are the absorbance of the maximum and the minimum, respectively.

ELISA assay

The cell culture medium was collected and used to measure HMGB1 levels by ELISA kits according to the manufacturer's suggested protocol. Absorbance at 450 nm was measured using a microplate reader.

Preparation of cell extracts

Nuclear and cytosolic extracts were prepared using nuclear and cytoplasmic extraction reagents, according to the manufacturer's instructions. The total protein extract was lysed in RIPA buffer and phenylmethylsulfonyl fluoride. The protein concentrations were determined by bicinchoninic acid assay.

Western blot analysis

Equal amounts of total cellular protein (20 μg per sample) were separated by SDS-PAGE and transferred to PVDF membranes that were blocked with

5% non-fat milk for 2 h and incubated with the primary antibodies overnight at 4 °C. The primary antibodies (diluted at 1 : 1000) used were as follows: anti-STIM1, anti-Orai1, anti-PLCγ1, anti-p-PLCγ1, anti-HMGB1, anti-PKCa, anti-CaMKIV anti-GAPDH, anti-β-actin, and anti-Histone H3 (1 : 500). The membranes were then washed three times (10 min/wash) with TBST and incubated with a 1 : 3000 dilution of goat anti-rabbit horseradish peroxidase-conjugated secondary antibody for 1 h at room temperature. After the final wash, the immunoreactive bands were detected on Fluor Chem E (Protein Simple) by enhanced chemiluminescence. The densities of bands were analysed using ImageJ software and expressed as ratios to β-actin or GAPDH or Histone H3.

Immunoprecipitation

A total of 500 μg of nuclear extract was incubated with 2 μg of anti-HMGB1 at 4 °C overnight on a rotator. Next, 30 μl of Protein A Agarose was spun briefly in a microcentrifuge at 500 g for 30 s and washed three times in PBS, then resuspended in 200 μl of PBS. A 40 μl slurry of Protein A agarose was added to each sample, followed by incubation for an additional 3 h at 4 °C on a rotator. The samples were spun briefly in a microcentrifuge at 500 g for 2 min and washed three times in PBS. Finally, the samples were resuspended in 40 μl of loading buffer for future analysis.

RNAi

We utilized the Smartpool siRNA from Dharmacon (Lafayette, CO, USA) that consists of four separate siRNA sequences against STIM1: GCGACTTCT GAAGAGTCTACC, GCTGCTGGTTTGCTATATCC, GCGGTTCCAGATTGTCA ATA and GGATTGACCAATTCGATTC, and a control siRNA NC: TTCTCCGA ACGTGTACGT. The LV3(H1/RFG&Puro)-STIM1 and NC constructs were constructed and identified by Shanghai UsenLab Biotechnology Co., Ltd. (Shanghai, China). Cells were plated in a six-well plate or confocal dish in 10% DMEM without antibiotics, resulting in 80% confluence before transfection. In separate tubes, 1.5 μg of each plasmid was diluted in 250 μl serum-free DMEM. Each solution was combined with 5 μl of Lipofectamine 2000 and mixed gently, and the final transfection mixture was incubated for 20 min at room temperature. The cells were transfected with STIM1-siRNA or NC-siRNA according to the manufacturer's protocol (Invitrogen, Carlsbad, CA, USA). Transfection efficiency was determined at 24 h by fluorescence microscopy, and mRNA and protein expression levels were measured 48 h after transfection.

Statistical analysis

Experiments were carried out in triplicate, and statistical analysis was performed using SPSS software. Significance between two groups was assessed using the paired or non-paired Student's *t*-test (*t*-test), and significance among multiple groups was assessed using a one-factor analysis of variance (ANOVA) with the Dunnett's *post hoc* test. *P* < 0.05 was considered as a statistically significant difference.
