REVIEW

Making the genomic leap in HCT: application of second-generation sequencing to clinical advances in hematopoietic cell transplantation

Yun R Li^{*,1,2}, John E Levine³, Hakon Hakonarson^{2,4,5} and Brendan J Keating^{*,2,4,5,6}

Recent developments in second-generation sequencing (SGS) technologies provide an avenue for achieving rapid and accurate high-throughput analysis of human and microbial genomic diversity. SGS technologies have the potential to transform existing medical management of complex and life-threatening medical conditions by enabling clinicians to develop disease-targeted clinical care plans for each patient. In this review, we outline how innovative SGS-based approaches can improve the care of recipients of allogeneic hematopoietic cell transplantation (HCT), a life-saving procedure that carries a 1-year mortality risk of over 30%. We specifically evaluate foreseeable applications of SGS-based technology in facilitating rapid, phase-sensitive human leukocyte antigen (HLA) typing, assessment of non-HLA genomic compatibility, identifying patients at high risk for adverse drug reactions, and post-HCT monitoring for engraftment, minimal residual disease and infection. We conclude that innovative SGS approaches have the capacity to revolutionize the HCT recipient risk assessment process, support non-invasive clinical monitoring and improve patient outcomes, thereby setting the stage for a new era of genomically informed patient-centered medicine.

European Journal of Human Genetics (2014) **22**, 715–723; doi:10.1038/ejhg.2013.247; published online 20 November 2013

Keywords: HLA; genomics; sequencing; GWAS; leukemia; SGS

INTRODUCTION

Approximately 60 000 hematopoietic cell transplantations (HCTs) are performed annually worldwide as the definitive therapy for a wide range of hematological malignancies and non-malignancies.¹ More recently, HCT has also been shown to be efficacious in a number of cell-based therapies for non-hematological conditions.^{2,3} Once a therapy of last resort for universally lethal diseases, a number of recent scientific and clinical advances, such as the introduction of molecular and sequence-based human leukocyte antigen (HLA) typing, have dramatically improved the long-term success rates of HCT. Despite this progress, the 1-year mortality rate among allogeneic HCT recipients remains a staggering 30–40%, making a potentially life-saving transplant risk-prohibitive for patients with significant comorbidities, at advanced ages, or for whom no appropriate HLA-matched donors can be identified.⁴

The degree of HLA matching between the donor and the recipient strongly determines the recipient's risk for graft-versus-host disease (GVHD), which alongside infection and disease relapse are the three major causes of transplant-related mortality (TRM).^{5,6} Unlike HLA matching, which is largely standardized across HLA laboratories at major transplant centers, other clinical aspects of HCT management, including pre-conditioning chemotherapy, prophylactic or therapeutic

antibiotic use and disease-relapse monitoring, vary significantly from center to center and by clinician experiences.

Integrating histocompatibility (including HLA) matching and other genomic markers for GVHD into cumulative risk models specific for a given patient's diagnosis, disease severity, and demographics offers a method for testing and establishing quantitative, evidence-based risk prediction algorithms. In the last 5 years, a number of prospective and retrospective analyses have reported the evaluation of combinations of genetic and clinical data (aside from HLA matching), in TRM/GVHD risk assessment. However, a clinically validated risk assessment algorithm that fully utilizes the available genomic data has not yet been developed or tested.^{7,8} While it may not always be possible to improve donor–recipient matching, as available donors are limited, quantitative, patient-specific risk scores can be useful in the clinical care setting. Accurate assessment and quantification of the underlying risk in relation to the frequency of monitoring of GVHD, infection risk and relapse can have major impact on HCT outcome and overall survival.

In the last decade, developments in the field of genomics, particularly the recent breakthroughs in second-generation sequencing (SGS)-based technologies, have stimulated the development of individual patient-based therapeutic approaches and methods for rapid and precise genetic testing. However, the full potential of these

advances in directing patient care are far from realized in the field of HCT. We present, in this review, a vision for how some of the forefront SGS technologies and approaches can improve the assessment of pre-transplant risk, individualize pharmacotherapy and inform long-term disease relapse monitoring (Figure 1). Although our review focuses on SGS applications to HCT, this is only one of many evolving models of how emerging genomics tools are empowered to deliver individualized patient therapy. As the technical aspects of most of the SGS technologies discussed here are expansive, we provide a brief summary and references for a wide range of SGS-based technologies that have been well-described elsewhere (see the technologies detailed in Table 1 and a brief overview of them in Box 1).

SGS APPLICATIONS TO HLA MATCHING

The HLA class I (A, B and C) and class II (DP, DQ and DR) molecules, encoded within the *MHC* (*Major Histocompatibility Complex*) on *chr6p21*, are codominantly expressed, cell-surface

receptors that serve dual functions. The HLAs, encoding the variable chains of the MHC receptors, present self and foreign peptide antigens to helper and cytotoxic T cells, and as a combination, make up a set of 'self-identifying' markers that are unique to a given individual. The clinical gold standard for identifying two individuals with matching HLAs at the amino-acid level, also known as high-resolution HLA matching, relies on either Sanger sequencing or other molecular tests to compare the genotypes at each of the eight (*HLA-A, B, C, and DRB1*) or ten (*HLA-A, B, C, DQB1 and DRB1*) highly polymorphic loci.⁹ An 8/8 HLA-matched HCT refers to a donor–recipient pair matched for *HLA-A, B, C, and DRB1*, whereas a 10/10 match also includes the *HLA-DQB1* locus.

While Class I HLAs are highly expressed across most somatic cells, Class II HLAs are predominantly expressed on the surface of professional antigen-presenting immune cells. Furthermore, while Class I antigens are composed of a polymorphic alpha chain and an invariable beta chain (encoded by a non-MHC gene

Figure 1 Clinical applications of second-generation sequencing (SGS) technologies to HCT. **(a)** Diagram of typical workflow from clinical sample to sequencing. SGS of genomic DNA derived from recipient somatic or tumor-cell DNA can be used to profile genomic risk factors of underlying disease or identify causative driver mutations in hematological malignancies. Although the exact methods are platform specific, typical SGS-based techniques follow a standard workflow, requiring the isolation of genomic DNA, DNA fragmentation and the ligation of paired-end adaptors. Depending on whether the whole genome, all coding or specific coding regions are interrogated, additional sequence-specific adaptors for exonic or user-specified regions are used to capture the prespecified target DNA fragments. Adapter-ligated fragments are next captured either in an oil-emulsion bead (454 pyrosequencing) or on a solid platform (bridge amplification) as shown here. All SGS techniques culminate with massively parallel sequencing technology utilizing an array-like platform. As nucleotide bases are added cyclically, light is produced and sequences are read out based on detected fluorescence intensities and wavelengths. **(b)** Existing and potential SGS applications to HCT patient care using available SGS technology: As discussed in the main text, SGS-based improvements to existing clinical care of HCT recipients can be broadly classified into three major domains: (1) accurate and rapid HLA typing, (2) pre-transplant assessment of adverse drug response and non-HLA genomic risk factors and (3) post-HCT early and routine monitoring for minimal residual disease, engraftment of donor cells, and life-threatening systemic infections.

Table 1 Genomics technology and methods discussed in this review

<i>Techniques</i>	<i>ABBR</i>	<i>Method</i>	<i>Existing research and clinical utility</i>	<i>Advances and limitations</i>	<i>Refs (PMID)</i>
Sanger sequencing		Sequencing by synthesis using fluorescently labeled nucleotides that terminate DNA strand elongation; automated using capillary electrophoresis	Routine laboratory and clinical sequencing today; 'gold standard' for sequence validation; high-resolution HLA typing and candidate gene sequencing	Draft sequence of the human genome; requires large quantities of DNA input; low sensitivity, limited resolution of heterochimerism	11237011 11181995
DNA or RNA microarrays		Nucleic acid fragments are allowed to bind allele-specific oligo probes (results are expressed as relative fold differences between sample and control)	High-throughput; low cost but requires sequence of target to be known; comparative analysis against controls (ie, gene expression changes pre/post chemotherapy)	DNA: GWAS or candidate SNP association studies RNA: Functional readout of cell activity by profiling the expression of specified genes	7569999 22289488 21527803
Genome-wide association study	GWAS	Microarray-based detection of SNPs; compares genome-wide SNP frequencies and correlates with known phenotypes	High-throughput, cost-efficient analysis of SNPs and CNVs once significance, LD, and frequency of common variants are known	<i>International HapMap Project</i> ; limited detection of rare and <i>de novo</i> SNPs; cannot detect indels	16369550 15761122 19474294
Second-generation sequencing	SGS	Sequencing by continuous complementary strand synthesis, millions of DNA fragments bound to platform, amplified by PCR, then sequenced in parallel	High-throughput; highly-sensitive compared to Sanger. Used for large-scale sequencing projects (ie, WGS, WES) or multiplex candidate gene sequencing (CAS)	<i>1000 Genomes Project</i> ; most widely used technique for large-scale sequencing	18846087 18846087
Third-generation sequencing	TGS	Single molecule sequencing without amplification of DNA. Multiple platforms (eg, nanopore, single polymerase seq, microscopy-based monitoring)	Eliminate the need to purify, fragment or amplify DNA; improved accuracy, throughput, sensitivity compared with SGS; same applications as SGS	Rapid pathogen identification without culture. Eliminates theoretical drawbacks of SGS; not yet widely available	20858600 22468954 21349208 21142692 21793740
Whole genome sequencing	WGS	SGS/TGS, sequencing of the total DNA content of a given DNA sample; no target enrichment. Can be of an organism, specific tissue, cell	Required for <i>de novo</i> assembly of unsequenced organisms; reassemblies of cancer cells. Microbiome sequencing. Expensive (\$3000/genome)	Best sequencing method to detect structural variations (ie, CNVs, translocations, duplications)	17803354 18421352 18987735
Whole exome sequencing	WES	SGS/TGS, same as WGS but 'baits' or adaptors are used to enrich for the protein-encoding regions (~1.5%) of the genome	More widely used than WGS because of lower cost (\$1000/exome); limited to protein-coding regions	Rare variant detection; identified mutations for hundreds of Mendelian disorders, limited detection of structural variants	1968457 19915526
Capture amplicon sequencing	CAS	SGS/TGS, same as WES but adaptors are designed to target candidate genes/regions on dozens of samples in 1 run by sample multiplexing	Analysis of a few 'panel genes'; most cost-effective for translation; available commercially and used in clinical trials	Strong clinical utility for deep coverage of a priori genes with high portion of genetic variance explained (eg, PGx)	22604722 21415896 21910929
Transcriptome or RNA sequencing	RNA-seq	SGS/TGS, absolute quantification of total cellular RNA, unbiased gene expression profiling + variant discovery; no prior sequence knowledge required	High-throughput, wide dynamic range, can extend to other RNAs (ie, miRNAs, lincRNAs, shRNAs, rRNAs, tRNAs); study RNA-editing, strand bias	ENCODE (Encyclopedia of DNA Elements) catalogs functional genome variation; cancer cell profiling, detect structural variations	18611170 19015660
Epigenomics		Array or sequencing analysis of non-coding DNA to understand nucleic acid organization, structure, regulation	Genome wide, high-throughput techniques to understand how DNA molecules are regulated. See below		23095436 22770212
Chromatin-immunoprecipitation sequencing	ChIP-Seq	SGS/TGS, WGS of DNA regions that are bound to specific chromatin regulating proteins (ie, transcription factors)	Identify binding sites of transcription factors or other chromatin-associated proteins	ENCODE; assess chromatin accessibility, imprinting, cell regulation in disease (e.g., cancer)	11237011 11181995
Whole methylome bisulfite Sequencing	WM-BSeq	SGS/TGS, WGS that allows specific and sensitivity detection of CpG cytosine methylation sites	Identify variations and locate regions under strong transcriptional regulation by differential methylation		21085693 22027613
DNAse sensitivity site sequencing	DNAse or Faire-Seq	SGS/TGS; WGS with specific enrichment for non-coding regions; identifies regions sensitive to DNAseI cleavage	Identify variations and locate regulatory regions, including enhancers, silencers, promoters, insulators, and locus control regions		20150147 16344561
Chromosome conformation sequencing	3C, 5C, Hi-C	SGS/TGS; WGS with specific enrichment for non-coding regions; assess topographical proximity of chromatin	Evaluates chromatin structure, long-range spatial organization of chromosomes resulting from epigenomic regulation	ENCODE; assess chromatin organization through cis and trans interactions (ie, enhancer and promoter interactions)	16369550 15761122 22215806

Genomic technologies and approaches are annotated and referenced with abbreviations that correspond with those found in the text. The *methods* column summarizes each technique and target application. The *existing clinical and research utility* column highlights the motivations for bringing this technology to the healthcare front and outlines, where present, existing clinical or research applications relevant to HCT. The *advances and limitations* column identifies notable applications and advantages of the method, along with any outstanding drawbacks to the platforms commercially available today.

Box 1 New genomics technology in HCT

Text (Box-1): A primer on genomic advances relevant to HCT: Since the publication of the first *genome-wide association study* (GWAS) in 2005, genome-wide array-based SNP genotyping has cataloged millions of common SNPs and CNVs across the human genome. Nearly 1900 GWAS have been published in the last 8 years, cumulatively identifying over 8000 genome-wide significant SNPs and CNVs associated with >300 different complex diseases and heritable traits.¹ Despite this enormous success in identifying novel genotype–phenotype associations, only a small proportion of total observed genetic heritability for most GWAS-investigated diseases can be explained by these reported loci. As the study design of GWAS is limited to identify common genetic variants that are thought to ‘tag’ rarer disease-causative variants, recent focus has shifted to large-scale genetic resequencing to identify rare coding mutations near or linked with candidate regions prioritized from GWASs.

Toward this end, *second-generation sequencing* (SGS) platforms have surpassed the throughput and speed of traditional Sanger sequencing by enabling the rapid sequencing of millions of DNA molecules in parallel (Box-1).² As with GWAS arrays, SGS begins with library preparation by fragmenting genomic DNA, which are then ligated to universal oligonucleotide adaptors. These adaptors facilitate the capture, or attachment, of the DNA fragments onto solid or bead-like platforms.³

Following capture, DNA fragments are clonally PCR amplified to generate ‘colonies’ of identical DNA fragments. Sequencing occurs by synthesis of the opposing, or complementary, DNA strand. Light is emitted when a specific nucleotide (typically fluorescently labeled) is incorporated. Because each colony, containing identical DNA molecules, is spatially defined on the array, light-based detectors can simultaneously detect the fluorescence at millions of array positions, producing millions of DNA sequence reads that correspond to the bases incorporated at each position in a massively parallel manner. See Figure 1.

The sequencing of the entire genome of an organism, or *whole genome sequencing* (WGS), has been used to generate *de novo* genome assemblies of cancerous cell genomes,⁴ numerous model organisms,⁵ the human gut microbiome⁶ and to identify rare disease-causing mutations.⁷ WGS, while comprehensive and necessary when there is no established reference sequence of an organism, is still relatively expensive. Moreover, since the biological function of the much of the non-protein encoding human genome has yet to be elucidated, functional annotation of many new (and existing) variants is difficult to interpret. This led to the development of *whole exome sequencing* (WES), a cost-effective alternative to WGS, where exonic sequence-specific ‘baits’ are used to capture the ~1.5% of the human genome that is protein-coding.⁸

The utility of WES was showcased in a seminal paper by Ng and colleagues in 2009 to identify the causative mutation underlying Miller’s syndrome,⁹ a rare Mendelian disease. Since 2009, a deluge of publications using WES have cataloged thousands of rare, private and *de novo* mutations in both rare and common genetic disorders. WES is likely to make a significant headway toward elucidating the cause of the ~3000 out of ~5000 Mendelian disorders for which the genetic etiology remains unknown.¹⁰ A major drawback to WGS and WES is the limited sequence lengths. Currently, the most widely used platform, which is based on bridge amplification, yields ~100–150 bp/reads.⁸ Limited read lengths make sequence assembly difficult, as the alignment of millions of 100 bp DNA fragments to produce a correctly ordered 3.5 billion bp sequence is computationally demanding and prone to alignment errors in repetitive regions. More expensive SGS platforms can provide reads over 600 bp in length, and emerging technologies are achieving much longer read lengths at greater fidelity relative to other SGS platforms.¹¹

As a complement to WES, *capture amplicon sequencing* (CAS) allows high-throughput, deep resequencing of custom-selected genomic regions (eg, custom panels of genes encoding drug metabolism enzymes).^{12,13} CAS exceeds the sensitivity of Sanger sequencing and is particularly useful for heterochimerism detection. For example, a mutation in a single cancer cell among a population of hundreds of normal cells can be identified using CAS. Efficient indexing techniques make it possible to use CAS to sequence the same set of genes in 50–100 samples at once. The high sample throughput capability of CAS will make this technique one of most affordable and clinically translatable approaches.

In addition to genome sequencing, *whole transcriptome or RNA sequencing* (RNA-seq) can provide genome-wide gene expression profiling.^{8,14} Compared with RNA microarrays, RNA-seq offers improved dynamic range and sensitivity for structural variations (eg, translocations).^{14,15} With the exception of an intermediate step to convert isolated RNA into cDNA, the wet-lab protocol for RNA-seq parallels that of WGS.

Finally, SGS methods can be used to study epigenetic modifications and transcriptional regulation. The understanding of epigenetic regulation in cancer has made new therapies available for the treatment of AML.¹⁶ Epigenomic techniques include whole methylome-bisulfate sequencing (WM-Bseq), chromatin-immunoprecipitation sequencing (ChIP-seq), open chromatin sequencing (DNase-seq, Faire-Seq), long-range genome interaction mapping (3C, 5C, Hi-C, Chia-PET).¹⁷

beta-2-microglobulin), Class II antigens are heterodimers composed of MHC-encoded alpha and beta chains, though the beta chains are typically more variable in sequence and consequently genotyped during clinical HLA matching. While *HLA* matching is critical for the success of allogeneic HCT, the degree to which a given mismatch will negatively predict outcome may vary depending on the antigen type, the relative antigenicity and expression level of a given HLA allele, as well as the underlying disease process and pre-conditioning regimen. Definitive and quantitative studies that assess these risk prediction models are still needed.

The ‘antigenic’ or hypervariable domains of the polymorphic chain of each HLA are accessible and recognized by corresponding T cells; the extreme diversity of the HLA repertoire in humans is, in part, attributable to the recent positive selection of this region in the human genome. Over the course of normal development, sequential processes of positive and negative selection enable T cells to accommodate the unique HLA repertoire of each individual, thereby facilitating self-tolerance. However, in the context of HCT, when donor T cells are introduced to the tissues of a ‘foreign’ recipient, any mismatching within these polymorphic regions will likely be strongly

immunogenic, often irrespective of the specifically bound antigen. This consequently may elicit cross-reactive donor T cells to mount an immune response to host tissues that clinically manifests as GVHD.

Acute GVHD (aGVHD), occurring within 100 days after transplant, can cause local inflammation to the skin, liver and gastrointestinal tract,¹⁰ but can also result in systemic tissue damage that is life threatening. The strongest predictor of aGVHD risk is the degree of HLA mismatching between the donor and the recipient,⁵ making the identification of an HLA-matched donor critical for the control and prevention of aGVHD. Compared with 8/8 HLA-matched HCT recipients, the risk of developing aGVHD is higher for one or two HLA-mismatched recipients.^{5,9} Since sequence-based *HLA* typing for donor selection became the standard of care at most transplant centers, short-term TRM has dramatically declined.⁶ Recent reports from the National Marrow Donor Program show that outcomes for HLA-matched, unrelated donor HCTs (MUD-HCTs) are now comparable to that of HLA-matched related donor HCTs (MRD-HCT), underscoring the critical importance of HLA matching in HCT outcomes.⁶

However, GVHD remains a major cause of morbidity and mortality, even after 8/8 and 10/10 MRD and MUD-HCTs, suggesting

that non-*HLA-A, B, C, DQB1* and *DRB1* genetic differences may be important in allorecognition. For example, *HLA-DP*, which is poorly expressed on the surface of lymphocytes, was not historically considered in matching.¹¹ However, in a 2012 retrospective analysis of nearly 12 000 HCTs using high-resolution *HLA* typing, Petersdorf *et al* showed that HCT transplants with *HLA-DPB1* non-permissive mismatching, as defined by T-cell epitope cross-reactivity groups, are significantly associated with poorer TRM in 10/10 and 9/10 MUD-HCT.¹² Similar studies on other classically 'low-expression' *HLAs* (including *HLA-C*, *DQ* and *DR51/52/53*) have also recently been shown to affect transplant outcome.^{13,14} These findings underscore the value of large-scale longitudinal analysis, the use of molecular and sequence-based *HLA* typing, and the increasing importance of non-classical *HLA* genes in HCT outcome as most allogeneic HCTs are now fully or near-fully *HLA* matched.

Under existing methods, typing additional *HLA* loci requires significant increases in time, effort and costs. However, a recent multi-center study demonstrated the efficiency and feasibility of highly accurate SGS-based *HLA* typing,¹⁵ showing improved accuracy, coverage and turn-around times of SGS at a comparable cost to lower resolution probe-based tests.¹⁶ Another drawback of existing methods is that most analyze only the highly variable exons of the typed gene to minimize cost. Consequently, non-synonymous single-nucleotide variants (nsSNVs) outside these targeted regions are missed. SGS makes targeted sequencing of entire *HLA* genes feasible with minimal increase in cost.¹⁷ In light of the recent findings that *HLA-DP* and other non-classical *HLA* mismatches also correlate with increased risk of TRM and GVHD, additional genetic information captured with SGS-based *HLA* typing may have clinical utility, particularly where multiple equivocally matched donors are identified based on classical *HLA* typing.

Finally, reflex testing is often required to resolve typing ambiguities that arise from Sanger sequencing, which does not yield phase information for heterozygous sites. In contrast, SGS-based *HLA* typing using tiled, paired-end primer designs accurately assess *MHC* haplotype phasing, thereby reducing the frequency of typing ambiguities and the need to perform reflex testing. As the throughput and read length of SGS continue to improve, soon it will be feasible to sequence the entire *MHC* in a few reads in just a few hours, eliminating time delay as a barrier to the use of *HLA* matching data to inform the treatment of solid organ transplant (SOT) recipients (eg, in pre-transplant immunosuppressive dosing).¹⁸

APPLICATION OF SGS TECHNOLOGY TO GVHD RISK ASSESSMENT BEYOND THE *HLA*

As the relative number of 9/10 and 10/10 MUD-HCTs performed have increased compared with less well-matched HCTs, it is becoming more clear that non-*HLA* genetic mismatching also underpin GVHD and overall TRM. For example, pediatric acute lymphoblastic leukemia (ALL) patients receiving MUD-HCT have a 2.42- and 5.12-fold increased risk of acute and chronic GVHD, respectively, compared with recipients of *HLA*-identical sibling donor transplants.⁹ Since donors and recipients from a MUD-HCT are *HLA*-matched by state, rather than by descent, the higher observed risk of GVHD among MUD-HCT *versus* MRD-HCT recipients could be attributable to non-*HLA-A, B, C*, and *DRB1* genetic disparities within and beyond the *MHC*.

In addition, Terasaki¹⁹ reported in a large retrospective analysis of rejection data from SOT that *HLA* mismatch accounted for just 18% of rejection risk, while 38% is attributable to non-*HLA* differences in genetic compatibility. In fact, sources of human genomic variations aside from the classical *HLAs* including non-synonymous SNPs

(nsSNPs), copy number variations (CNVs) and nucleotide insertion/deletions (indels) in genes encoding cell-surface proteins are known to contribute to the 'non-*HLA*' histocompatibility repertoire.²⁰ These include genes that encode the Killer-cell Immunoglobulin-like Receptor family members (KIRs), *MIC-A* and *MIC-B* antigens,²¹ and minor histocompatibility antigens (mHAs).

The mHAs, a group of polymorphic peptides that can be presented by specific *MHC* molecules to mediate T-cell allorecognition in the context of *HLA*-matched transplants, are encoded as nsSNPs or other genetic variations across ~50 (as of 2012) autosomal *mHA* genes.¹ In addition, there are Y-chromosomally encoded mHAs (H-Y antigens), for which mismatching has been shown to increase the GVHD and TRM risk in recipients of female-to-male MRD-HCTs (F-to-M), as compared with non-F-to-M recipients.^{22,23}

That only a few dozen mHAs are known is surprising given the sequence diversity of the human genome. Depending on ancestry and relatedness, two humans have ~3–10 million divergent variants, or one base-pair difference per 300–1000 bases. As 3–5% of these polymorphisms are in coding regions of the genome, many more mHAs may exist but have remained unrecognized.²⁴ As mHAs were historically identified using biochemical means, state of the art genomic or proteomic screens may reveal the existence of many more mHAs.²⁵

Recent efforts using high-throughput genomics, *in-silico* prediction and candidate gene resequencing have already yielded some successes,²⁶ for example, in the recent discovery of histocompatibility genes that occur as a result of functional gene expression knockout by McCarroll *et al*.²⁷ Such genes encode gene-expressed mismatch antigens (GEMAs), which are not expressed in a significant percentage of the human population due to the presence of two non-complementary null mutations at a single locus (Figure 2). In the context of transplantation, when donors and recipients are mismatched in the expression of a GEMA, GEMA-derived peptides are antigenic in the GEMA(–) individual. Analogous to the role of H-Y antigens in F-to-M HCT transplants, GEMA mismatch can thus cause GVHD in HCT recipients if GEMA(–) donor lymphocytes are transplanted to a recipient whose somatic cells are GEMA(+).

Identifying GEMAs and other genomic loci that contribute to allogeneicity may also identify donor–recipient genetic disparities that are beneficial, such as the KIRs, which are encoded by a cluster of highly polymorphic and copy number variable genes at *chr19q13.4*.^{21,28} KIRs negatively regulate the activity of NK cells when they are stimulated by their cognate ligands, the NK-inhibitory ligands encoded within the *MHC*. *KIR* mismatching in the context of MRD-HCTs or MUD-HCTs results in the disinhibition of KIRs, since the donor NK cells are not suppressed by the ligands expressed in a *KIR*-mismatched recipient. The disinhibition of NK cell activity appears to improve survival among patients receiving *KIR*-mismatched, *HLA*-matched HCTs for lympho- and myeloproliferative diseases by boosting the graft-*versus*-leukemia (GVL) effect.^{29,30} As the genetic inheritance of *KIRs* and the *MHC* loci are independent meiotic events, on average 75% of MRD-HCT and nearly all MUD-HCTs are *KIR* mismatched. Other GVHD-protective genomic markers may exist with similar or disparate mechanisms, and identifying them may benefit from creative applications of unbiased genomic studies among large MRD/MUD-HCT cohorts. However, such non-*HLA* effects, albeit clinically significant, may be minor relative to the effect of *HLA*, or could be *HLA*-dependent.

Although the use of non-*HLA* factors in donor selection may not be practical given the limited donor availability, identification of polymorphisms in mHAs, GEMAs or immunoregulatory genes that

Figure 2 The role of gene-expressed mismatch antigens in GVHD or rejection following transplantation. **(a)** Donor-recipient GEMA mismatch in myeloablative HCT: GVHD can occur in an HCT recipient with normal GEMA expression when he or she is transplanted with cells derived from a donor without normal GEMA protein expression. Since GEMAs are ‘self-expressed’ antigens, GEMA-derived peptides can be presented in the context of both class I and class II MHC receptors found on recipient cells following HCT. Allorecognition of host MHC molecules presenting GEMA-derived peptides subsequently triggers donor-derived T cells that are not ‘tolerized’ to GEMA-derived peptides to attack host cells, resulting in clinical manifestations of GVHD. In addition, because GEMAs such as UGT2B17 can be cell-surface antigens, their antigenicity is not MHC-restricted like most autosomally encoded minor histocompatibility antigens. Like H-Y antigens, a B-cell mediated response to the ‘foreign’ GEMA expression can result in the production of autoantibodies by donor-derived B cells that target the host-cell expressed GEMA proteins on the cell surface. McCarroll *et al.* first demonstrated the clinical significance of GEMA mismatch in HCT by following up on the results from a large genome-wide association study (GWAS)-based screen for homozygous deletion copy number variations (hdCNVs) that appear to be tolerated and are found frequently in an appreciable percentage of the human population. Based on the hypothesis that hdCNVs overlapping a gene-encoding region would cause gene expression mismatch between HCT donors and recipients, McCarroll screened ~400 HCT recipients and their HLA-matched siblings for six candidate GEMAs. They identified that D-/R+ status for one particular GEMA UGT2B17 increased the risk of Grade 2+ GVHD, a finding that was later replicated in two independent cohorts, together totaling over 1300 patients (combined OR of 2.5).¹⁸ In addition, McCarroll *et al.* showed that UGT2B17+ HCT recipients, who received hematopoietic cells from UGT2B17-/- donors were seropositive for anti-UGT2B17 antibodies. Moreover, they were able to isolate MHC-bound UGT2B17-derived peptides from the sera of these UGT2B17 mismatched. Given that the average human genome has at least several thousand CNVs greater than 1 kb (which is likely to be an underestimate due to current limitations in CNV detection platforms¹⁹) and contains ~100 loss of function (LoF) mutations (with ~20 in both copies)²⁰, other GEMAs are likely to exist. By coupling large-scale RNA-seq and SGS data, a genome-wide search for other GEMAs may reveal hundreds of other such loci across the genome. **(b)** Donor-recipient GEMA mismatch in the context of reduced-intensity conditioning/non-myeloablative HCT or solid organ transplantation: rejection of donor cells or tissue occurs due to the absence of GEMA protein expression (eg, UGT2B17) in the recipient. Complementary to the scenario illustrated in **(a)**, recipient tissues do not express GEMA proteins. Thus, potentially GEMA-reactive T- and B-cell clones are not eliminated from the host immune repertoire. Following transplantation, immune competent recipient T cells can attack donor stem cells expressing GEMA and inhibit engraftment or cause acute graft rejection.

are important for HCT outcome can be used to develop a multi-factorial GVHD and TRM risk assessment model.^{7,26,31} Such a model will need to differentially weigh HLA and non-HLA factors based on their ability to predict the likelihood and severity of TRM and GVHD. As allele-level *HLA* typing and non-*HLA* genetic data are now cataloged for patients across large allogeneic HCT recipient databases, multi-variate risk prediction algorithms developed using complex and large-scale genomic data may enable the development of risk-prediction algorithms. Definitive evaluation of clinical implications of these findings will require careful analysis of results from large randomized, clinical trials that test the utility of prospective risk-stratification efforts.

APPLICATION OF PHARMACOGENOMICS (PGX) TO HCT

Dozens of GWAS and RNA expression studies published in the last decade have identified dozens of significant associations between the presence of genetic polymorphisms and changes in gene expression to the risk of adverse drug response (ADR), respectively. For example, ~1 in 300 individuals have complete LoFs (null mutations on two copies) in the gene encoding thiopurine methyltransferase (*TPMT*), the hepatic enzyme required for 6-Mercaptopurine (6-MP) degradation. Administering standard 6-MP doses to ALL patients with underlying *TPMT* deficiency causes life-threatening ADR.³² Currently, *TPMT* genotyping can be routinely ordered before chemotherapy to identify those at risk for ADR, but also to identify heterozygous *TPMT* mutation carriers, who show improved response rates to 6-MP treatment compared with patients with two normal copies of *TPMT*.³³

In addition to *TPMT* and other-characterized examples of ADR, studies applying large-scale SGS and GWAS screening methods have identified a number of rarer mutations in proteins either directly or indirectly involved in drug metabolism or enzyme synthesis that increase the risk of ADR or significantly affect therapeutic outcomes. Toward this end, GWAS has been particularly successful in identifying pharmacogenetic (PGx) loci by SNP genotyping and expression quantitative trait loci (eQTL) analysis. Notable examples include mutations in *Interleukin-15* (*IL15*) associated with altered disposition of antileukemic chemotherapy (pediatric ALL), as well as those in *CYP2C9* associated with bisphosphonate-induced jaw osteonecrosis (multiple myeloma), among others^{34–36} (see Table 2 for a detailed list of known PGx loci). In part, the success of GWAS is related to the fact that many ADR-associated mutations are relatively common in the population, since these ‘evoked’ phenotypes are otherwise not deleterious, such mutations are typically not under negative selection pressure.

By enabling clinicians to make informed, patient-specific therapeutic choices that favor therapeutic response while minimizing ADRs, PGx knowledge may lead to a significant life and cost-savings. Approximately 20% of all injuries and deaths among hospitalized patients in the United States has been attributed to ADRs,³⁷ incurring an annual event-related health-care cost of over 136 Billion USD.³⁸ Since the rate of ADRs rises exponentially among patients receiving four or more medications,³⁹ evaluating and minimizing ADR risk is particularly important for HCT recipients, who are exposed to high doses of multi-drug combinations over the course of therapy.

An excellent implementation of PGx in direct patient care is exemplified by the Electronic Medical Records and Genomics (eMERGE) Network pilot program, which integrates the results of capture amplicon sequencing (CAS), a form of targeted SGS, of 84 key PGx genes into patient electronic medical records (EMRs) that are directly accessible to treating physicians. This initiative is part of an evolving effort to improve the portability and accessibility of genomic

Table 2 Pharmacogenomic (PGx) discoveries relevant to HCT patient management

<i>Gene</i>	<i>Specific drug implicated</i>	<i>Clinical correlates of polymorphism</i>	<i>Method of identification</i>	<i>Patient cohort studied</i>	<i>Reference (PMID)</i>
<i>TPMT</i>	Thiopurines (azathioprine, 6-MP)	(homo) toxicity (het) lower risk of detectable MRD	Candidate	ALL	10580024
<i>CNTNAP2, LEPR, CRHR1, NTAN1, SLC12A3, ALPL, BGLAP, APOB</i>	Glucocorticoids	Hypertension	Candidate	ALL	18496130
<i>CYP2C8</i>	Bisphosphonate	Jaw osteonecrosis	GWAS	Multiple myeloma	18594024
<i>IL15</i>	RIC	Likelihood of sustained MRD	GWAS	ALL	19176441
<i>CYP3A5</i>	Tacrolimus	Toxicity, EFS	Candidate	ALL	22215203
<i>ABCB1</i>	Cyclosporine	Nephrotoxicity	Candidate	Renal transplant	15772250
<i>DPYD, TYMS, GSTP1, ABCC2</i>	Fluoropirimidine and oxaliplatin	Mucositis, neutropenia, GI toxicity	Candidate	Multiple cancers	23047504
<i>VDR, CYP3A5</i>	Induction therapy	GI toxicity/infection	Candidate	ALL	17264302
<i>CYP2C9</i>	Cyclophosphamide	Toxicity	Candidate	Thalasemia major	22231460
<i>TYMS, VDR, PAI-1</i>	Glucocorticoids	Osteonecrosis	Microarray	Pediatric ALL	15459215
<i>ABCC2</i>	Methotrexate	Plasma concentration	Candidate	ALL	17112803
<i>SLCO1B1</i>	Methotrexate	Disposition	GWAS	ALL	22147369
<i>ACPI</i>	GC	Osteonecrosis	GWAS	Pediatric ALL	21148812
<i>CYP2B6</i>	Cyclophosphamide	Toxicity	Candidate	Leukemia	19005482
<i>MTHFR</i>	Busulfan	Hyperbilirubinemia	Candidate	Adult HSCT	18214047
<i>ITPA</i>	Cyclophosphamide				
	Mecaptopurine	Reduced drug metabolism, febrile neutropenia	Candidate	Pediatric ALL	20021291
<i>DHFR</i>		EFS	Candidate	Pediatric ALL	19861437
<i>VDR</i>		TRM	Candidate	Leukemia	19005482
<i>MTHFR</i>		Mucositis	Candidate	Pediatric ALL and malignant lymphoma	21509569
<i>TYMS</i>		TRM	Candidate	ALL	11937185
<i>MTHFR, TYMS</i>		Increased risk of relapse	Candidate	Pediatric ALL	15781665

Abbreviations: ALL, acute lymphoblastic leukemia; EFS, event-free survival; GC, glucocorticoids; GI, gastrointestinal; HCT, hematopoietic stem cell transplant; MRD, minimal residual disease; TRM, transplant-related mortality.

Method of identification refers to the original technology/approach used to discover the association. Patient cohort refers to the original patient population in which this variant was first shown to be linked to variation in drug response. Where blank, no specific drug was reported in the study.

information to facilitate individualized patient care, in the hope of improving long-term and peri-operative ADR risk management.⁴⁰ By limiting the total number of loci interrogated, CAS allows panel-based multiplex genetic testing of selective loci at high-throughput with improved cost efficiency. CAS is particularly suited as a clinical tool for the assessment of a set of informative genes, such as enzymes that act in drug metabolism. In the context of HCT, a CAS panel developed for pre-transplant risk assessment that includes PGx and non-MHC histocompatibility loci may be a viable option until WGS and ES become available economically on a large scale.

SGS APPLICATIONS IN POST-TRANSPLANT MONITORING

Sensitive detection of donor–recipient cellular chimerism, minimal residual disease (MRD), and early stages of microbial infections are critical to post-HCT clinical care, particularly in patients with underlying malignancy. Existing surveillance methods aimed at early detection of cancer cells in post-HCT chimeric hematopoietic systems rely on STR typing with an ~2–3% detection limit. Several groups have reported the successful application of SGS technology to achieve improved detection sensitivity for low copies of genomic DNA that are the minor component in mixed cellular or acellular samples, including sera.

Compared with molecular and Sanger sequencing-based methods, SGS is sensitive enough to detect mutations in single tumor cells,^{41,42} which is the ultimate goal of MRD detection. For example, CAS-based profiling of total genomic DNA isolated from the peripheral blood of breast and ovarian cancer patients has been used for routine monitoring of patients who achieved disease remission. This non-invasive method has been shown to detect *TP53* (P53) and *EGFR* mutations during early stages of cancer relapse by detecting rare cancer-specific polymorphisms (MAF ~2%) at sensitivities and

specificities >97%.⁴³ SGS has also been used clinically to diagnose hematopoietic malignancies and inform cancer immunotherapy. Another study has shown that exonic mutations in a select set of cancer genes, including *TP53* and *RUNX1*, improved prognostic significance in 439 patients with myelodysplastic syndrome.⁴⁴ Coupling single-cell isolation methods such as flow cytometry with CAS or WGS could enable MRD monitoring at sensitivities and specificities beyond that achievable by existing methods.⁴² For instance, Wu *et al*⁴⁵ have shown, using SGS of variable regions of *T-cell Receptor Beta* and *Gamma* (*TCRB* and *TCRG*) genes of patients with T-lineage ALL, superior detection of early disease relapse compared with established flow-based methods.

Furthermore, SGS methods have been applied to the management of post-transplant recipients, including the non-invasive detection of acute cellular rejection following heart transplantation. By monitoring the levels of donor genomic DNA levels in the sera of recipients, Synder *et al*⁴⁶ accurately predicted if the recipient is experiencing early stages of acute graft rejection. Others have shown that combined PCR and SGS quantification of T-cell repertoire recovery can successfully predict which patients are at high risk of infection or disease relapse following HCT.⁴⁷

Finally, early detection and therapy of microbial infections are crucial determinants of HCT outcomes as >30% of HCT recipients develop an episode of bacteremia in the first weeks following transplant and 15% of all mortalities following unrelated allogeneic HCT are infection related.⁵ Rapid and accurate detection, identification and drug-susceptibility phenotyping methods for isolated clinical pathogen(s) using WGS and CAS of non-human DNA or RNA^{48,49} using genomic or ribosomal multi-locus sequence typing (MLST/rMLST) already exist. In one approach, for example, a

CAS panel of 53 bacterial genes that encode the bacterial ribosome protein subunits uniquely catalogs >1900 bacterial genomes from 452 bacterial genera. Sequences derived from clinical isolates can then be queried against this database for rapid strain-level identification.⁵⁰

Unlike RT-PCR or array platforms, SGS detects a wide range of pathogens in a single test, eliminating single pathogen tests. This method is particularly helpful for the early detection and typing of fungal infections, which remain a major cause of morbidity and mortality in immunocompromised HCT recipients. With few exceptions, fungal typing requires the culture of slow-growing organisms, making rapid diagnosis within an already narrow therapeutic time-window challenging (eg, *Mucor*).⁵¹ Although SGS of clinical microbial samples currently requires an intermediate culture and isolation step, metagenomic approaches using third-generation sequencing (TGS) are currently being developed. These TGS platforms do not require amplification or culturing, and affords single DNA molecule sequencing of samples directly acquired from body fluids or sample sites.^{49,52}

In addition, SGS can be coupled with PGx to improve antimicrobial selection and dosing by detecting high-resistance strains that require strain-specific therapy and reducing the frequency of severe ADRs to anti-microbial agents. SGS has already transformed clinical practices in the care of highly virulent infections such as HIV. Over 300 000 HIV-1 strains have been sequenced worldwide and matched with drug-susceptibility data, providing a large electronic database that matches HIV DNA sequences of a patient-specific infection to drug susceptibility patterns. This resource enables physicians to prescribe individualized HAART (highly active anti-retroviral therapy) regimens for patients based on the drug resistance pattern predicted for their virus.⁵³ A similar strategy has also been efficacious in using SGS to identify *MRSA*, influenza, or specific pathogenic *E. coli* strains from related, but benign strains.^{54,55}

FROM RESEARCH FINDINGS TO CLINICAL DELIVERABLES

Since the first draft human genome was completed, requiring \$3 billion USD over 13 years, the technological and scientific advances that have been made in human genetics have exponentially accelerated. Indeed, SGS can now accomplish the equivalent task in <30 h for the cost of a magnetic resonance imaging scan (~2–3000 USD).^{18,56} Although the clinical implementation of SGS technology to routine patient care will require significant upfront costs in equipment acquisition and personnel training, these investments will be worthwhile. In fact, three companies have released bench-top SGS instruments intended to reduce the cost of SGS technology and to increase their accessibility at smaller institutions.¹⁸ These portable technologies can sequence an entire human genome (100 × the size of that of the average *E. coli*) in just 15 min to 3 h.⁵⁷ Such a timeframe makes the use of SGS for infection or MRD monitoring feasible over the course of a clinic visit or on the hospital floor.

Taken together, SGS can be used to provide pre-HCT histocompatibility, ADR and GVHD risk assessment. As illustrated in Figure 3, the use of CAS or WGS as a part of post-HCT care also enables high-sensitivity engraftment assessment, infection detection and disease relapse monitoring. Although the expense of SGS methods is not trivial, a single allogeneic HCT and peri-procedural care cost on average over 200 000 USD; in comparison, the cost of WGS is fast approaching 1% of this sum.⁵⁸ The real challenge is thus not necessarily cost, but rather in determining how to streamline SGS-based methods for clinical applications and concretely defining how genomic information should be appropriately used in the patient-care setting.

In the coming years, physicians can use SGS to prospectively acquire genomics information about a recipient and potential donor(s), and thereby, refine donor choice, assess GVHD risk and facilitate individualized chemotherapy. Post-HCT applications of SGS can expedite MRD monitoring and infection diagnosis. Together, this

Figure 3 The application of genomics approaches to improve HCT outcomes. (Left) panels show existing clinical practice, (Center) panel describes recent scientific/research contributions through genomic technology and (Right) panel proposes clinically feasible applications of genomics technology in the coming years. The four categories correspond to the four areas in which genomics technology will likely make the most direct impact on the clinical management of HCT recipients.

suite of advances in HCT recipient management exemplifies the versatility of SGS-based genomics applications in delivering personalized, evidence-based patient care.
