SHORT REPORT

Genome-wide linkage analysis and whole-genome sequencing identify a recurrent *SMARCAD1* variant in a unique Chinese family with Basan syndrome

Basan syndrome is a rare autosomal dominant genodermatosis, characterized by rapidly healing congenital acral bullae, congenital milia and lack of fingerprints. A mutation in the *SMARCAD1* gene was recently reported to cause Basan syndrome in one family. Here, we present a large Chinese family with Basan syndrome; some patients presented with hyperpigmentation and knuckle pads in addition to previously reported clinical manifestations. We used genome-wide linkage analysis and whole-genome sequencing (WGS) to identify the pathogenic gene in this unique pedigree. Genome-wide linkage analysis successfully mapped the candidate gene to 4p15.31-4p14 and 4q13.2-4q23. The maximal LOD score was 3.01. WGS in one patient identified a splice variant (c.378+1G>T) in the *SMARCAD1* gene (NG_031945.1) that was confirmed by Sanger sequencing. Co-segregation of the variant was confirmed in this pedigree. The same variant was recently found to be associated with isolated adermatoglyphia (ADG) in another family, suggesting that this variant is causative for both Basan syndrome and autosomal dominant ADG (OMIM 136 000). This indicates that ADG and Basan syndrome may be the phenotypic variants of the same disease. Further studies should be performed to elucidate the pathogenic mechanisms induced by this variant. This report increases the phenotypic spectrum of Basan syndrome and furthers our understanding of the genetic basis of this disease. Our results also highlight the power of combining WGS and genome-wide linkage analysis in identifying causative genes in pedigrees with a genetic disorder.

European Journal of Human Genetics (2016) **24**, 1367–1370; doi:10.1038/ejhg.2016.15; published online 2 March 2016

INTRODUCTION

Basan syndrome is a rare genetic skin disease with autosomal dominant inheritance that is characterized by rapidly healing congenital acral bullae, congenital milia and lack of fingerprints.¹ Other phenotypes include contractures of digits, hypohidrosis, palmoplantar keratoderma (PPK) and nail dystrophy.² Nine pedigrees with Basan syndrome have been reported worldwide.^{3–10} Recently, Marks *et al.*¹⁰ identified *SMARCAD1* (OMIM 612761) as a promising candidate gene for Basan syndrome in an American family. This gene encodes a member of the SNF subfamily of helicase proteins.⁹ Variants in the *SMARCAD1* gene were previously reported in patients with adermatoglyphia (ADG, OMIM 136000), which is characterized by the congenital absence of epidermal ridges.^{11,12} To date, five variants (c.378+1G>T, c.378+1G>A, c.378+2T>C, c.378+3A>T and c.378+5G>C) have been reported in patients with ADG and Basan syndrome. These variants were all found in splice sites of a short, skin-specific isoform of the gene.^{10–12}

In this paper, we describe a large pedigree with Basan syndrome and reveal the causative gene through genome-wide linkage analysis and whole-genome sequencing (WGS).

SUBJECTS AND METHODS

Patients

We investigated a 3-year-old girl with Basan syndrome from the Henan province of China. She had acral bullae on the fingers and soles

of the feet at birth, which were completely healed by two months of age. Milia were prominent on the forehead, nose and around the mouth. Upon examination, her hands had a leather-like texture and transverse palmar creases were observed with increased fine wrinkling (Figure 1a). She had knuckle pads on the dorsal side of her hands (Figure 1b). She lacked sweating on her hands and feet. The hair, eyebrows, eyelashes, teeth and nails were all normal. Her mother and cousin were also affected, with knuckle pads on the dorsal side of their hands and hyperpigmented macules on the hands and feet (Supplementary Figures 1a and b). In total, eight individuals were affected in this family and all affected individuals presented with similar clinical manifestation (Figures 1c–e) (Table 1). The pedigree of the family is shown in Figure 1f.

Genomic DNA was extracted from peripheral blood samples of the eight affected and eight unaffected family members. Informed consent was obtained from all participants and approval was obtained from the ethics committee of the Shanghai Jiaotong University School of Medicine and was conducted in accordance with the principles of the Declaration of Helsinki.

Genome-wide linkage analysis

Approximately 200 ng of genomic DNA from each of the 16 participants was genotyped using an Illumina Infinium Human OminiZhongHua-8 whole genome array (Illumina, San Diego, CA, USA). Genome-wide linkage analysis was performed with a total of 900 015 SNP markers. SNPs with a call rate of <90% and monomorphic or non-Mendelian-transmitted markers were removed.

Table 1 Clinical manifestations of this pedigree with Basan syndrome

	Skin blistering	Congenital milia	Lack of fingerprints	Contractures of digits	Hypohidrosis	PPK	Nail dystrophy	Hyperpigmentation	Knuckle pads
II:3	+	+	+	Severe	+	Severe	+	+	Mild
III:1	+	+	+	Moderate	+	Moderate	–	+	Mild
III:4	+	+	+	Severe	+	–	–	+	Severe
III:6	+	+	+	Mild	+	–	–	–	–
IV:1	+	+	+	Mild	+	–	–	+	Severe
IV:2	+	+	+	Mild	+	–	–	+	Moderate
IV:4	+	+	+	Mild	+	–	–	–	Severe
IV:5	+	+	+	Mild	+	–	–	–	Severe

Abbreviation: PPK, palmoplantar keratoderma.

A total of 11 152 informative autosomal SNPs within an average genetic distance of 0.25 cM were retained in the linkage analysis. Multipoint parametric linkage analysis was performed using MERLIN program version 1.1.2 software (Ann Arbor, MI, USA). A fully

penetrance autosomal dominant model was used with a rare disease frequency of 0.0001. Critical recombination events of the pedigree were also determined through haplotype construction using the MERLIN software.

Exome sequencing and whole-genome sequencing

We performed exome capture using Agilent SureSelect Human All Exon Kits (Agilent, Santa Clara, CA, USA) according to the manufacturer's instructions. Sequencing was performed on a HiSeq 2000 platform with read lengths of 100 bp. The mean coverage depth for each sample was 100×. The sequencing reads were aligned with the NCBI human reference sequence.

For whole-genome sequencing, paired-end DNA libraries were prepared according to the manufacturer's instructions (Illumina Truseq Library Construction (Illumina)). Genomic DNA (1.5 µg) was sheared into 350 bp fragments in a Covaris S220 sonicator (Woburn, MA, USA). DNA libraries were sequenced on an Illumina HiSeq X according to the manufacturer's instructions to generate paired-end 150 bp reads. Variants with a minor allele frequency (MAF) of >1% were filtered in the dbSNP databases and variants with a MAF >0.5% were filtered in the 1000 Genomes databases (1000 Genomes Project Consortium). Only SNPs occurring in exons or in canonical splice sites were further analyzed. The functional relevance of the detected variants was assessed using SIFT and PolyPhen-2 programs. Variants with SIFT scores of <0.05 and PolyPhen-2 scores of >0.95 for PolyPhen-2 were regarded as functionally relevant.

Sanger sequencing

We designed primers flanking all coding exons and intron–exon boundaries of *SMARCAD1* (NG_031945.1) using Premier 5.0 software (Palo Alto, CA, USA). All PCR products were purified using a QIAquick PCR Purification Kit (Qiagen, Hilden, Germany) and sequenced using an ABI PRISM 3730 automated sequencer (Applied Biosystems, Foster City, CA, USA). The *SMARCAD1* variant c.378+1G>T was submitted to the Leiden Open Variation Database (LOVD) at <http://databases.lovd.nl/shared/individuals/00057917>.

RESULTS

Linkage analysis

The affected patients in this pedigree had acral bullae on the fingers and soles of the feet at birth, which followed a similar manifestation as epidermolysis bullosa simplex (EBS, OMIM 131900). For this reason, we excluded mutations in the keratin 5 gene (*KRT5*, OMIM 148040). After confirming the exclusion of *KRT5* mutations by Sanger sequencing, we performed a genome-wide linkage scan using SNP markers. LOD scores were calculated under the assumption of autosomal dominant inheritance with a penetrance of 100%. Linkage and haplotype analyses mapped the pathogenic gene in this family to two loci. One mapped region was 4p15.31–4p14, located between rs1378946 and rs1435378 (Supplementary Figure 2a). The other region was 4q13.2–4q23, located between rs6840820 and rs6818863 (Supplementary Figure 2b). Maximal LOD scores were all 3.01 (Figure 2a) (Supplementary Table 1). No other locus of suggestive linkage was detected.

Exome sequencing and whole-genome sequencing

We performed exome sequencing in one affected individual and found no functional variants in the mapped regions. WGS using the Illumina HiSeq XTen platform with an average coverage of 27.94 reads per base identified 3 832 626 variants (SNVs and short indels). After filtering of the identified heterozygous variants through the 1000 Genomes Project, HapMap 8 and dbSNP135 databases, two variants remained within the mapped region. These included the splice variant c.378+1G>T in a splice site of the *SMARCAD1* gene (RefSeq NG_031945.1) and a duplication of GGC at position 328 330 (c.328_330dup) in exon 1 of the *ANKRD17* gene (RefSeq NM_032217.4). We found that the splice variant c.378+1G>T was not covered by whole-exome sequencing.

Figure 2 (a) Output of chromosome 4 multipoint LOD score analysis. (b) Normal sequence of the *SMARCAD1* gene. (c) Mutation of the *SMARCAD1* gene in this family. The black arrow indicates mutation.

Sanger sequencing

The splice variant in *SMARCAD1* was confirmed by conventional sequencing and co-segregated with the phenotype in this family (Figures 2b and c). It was not found in any of the 100 healthy controls, suggesting it is an uncommon variant with functional relevance. The non-frameshift variant found in the *ANKRD17* gene did not co-segregate with the phenotype in this family.

DISCUSSION

ADG is a rare heritable disorder, which may present as an isolated feature,^{3,12} but is often characterized by additional manifestations, such as skin blisters, congenital milia, hypohidrosis, nail dystrophy, palmoplantar keratoderma and contractures of digits.^{1,2,4,5,10} Some complex syndromes also present similar symptoms to ADG, such as Naegeli–Franceschetti–Jadassohn syndrome, dermatopathia pigmentosa reticularis or Basan syndrome.^{1,13–15} In this study, some patients presented with hyperpigmentation and knuckle pads in addition to previously reported clinical manifestations. This report has increased the phenotypic spectrum of Basan syndrome.

Only five variants in the *SMARCAD1* gene have been identified in patients with isolated ADG or Basan syndrome so far (c.378+1G>T, c.378+1G>A, c.378+2T>C, c.378+3A>T and c.378+5G>C).^{10–12} These variants disrupt a single conserved donor splice site and are predicted to result in haploinsufficiency by reducing protein translation in affected patients.¹² In this pedigree with Basan syndrome, we detected a recurrent splice variant, which has been reported in a Swiss family with isolated autosomal dominant ADG.¹² Affected individuals in this family presented with rapidly healing congenital acral bullae, congenital milia, lack of fingerprints and other clinical features. This suggests that ADG and Basan syndrome may be phenotypic variants of the same disease.

Marks *et al.*¹⁰ reported a splice variant (c.378+3A>T) in a family with Basan syndrome and seven individuals were affected over four generations. These patients presented with congenital absence of fingerprints and a history of facial milia during the newborn period; but only three affected members had rapidly healing skin blisters, and two affected individuals had palmoplantar callosities and lacked sweating on their hands and feet. In this Chinese family, we report skin blistering, congenital milia, lack of fingerprints, contractures of digits and hypohidrosis in all eight patients; but only II:2 and III:1 presented with PPK and only II:2 had nail dystrophy. Five affected individuals (II:1, III:1, III:4, IV:1 and IV:2) presented with hyperpigmentation on the dorsal side of the hands. Excepting III:6, all patients presented with knuckle pads (Table 1). These results indicate that the same variant leads to different phenotypes even within the same family, suggesting that environmental factors such as sunlight, pressure, ethnic differences, modifier genes or polymorphic sequences of *SMARCAD1* may play an important role. Further investigation is required to elucidate the pathological mechanisms leading to the phenotypes associated with the skin-specific isoform of *SMARCAD1* in this family.

In conclusion, we have reported a splice variant in the skin-specific isoform of the *SMARCAD1* gene that is associated with Basan syndrome. To our knowledge, this represents the second family with a splice variant that is causative for Basan syndrome. This report has advanced our understanding of the genetic basis of Basan syndrome and enlarges the phenotypic spectrum of this disease. The ongoing identification of causative variants may provide further insight into the mechanisms underlying the development of this disorder.
