Abstract

Purpose The purpose of this study was to review the microbiological profile, *in vitro* antibiotic susceptibility and visual outcomes of paediatric microbial keratitis in Shanghai, China over the past 6 years.

Methods Medical records of patients aged ≤ 16 years were reviewed, who were diagnosed as having bacterial keratitis between 1 January 2005 and 31 December 2010. Bacterial culture results and *in vitro* antibiotic susceptibility were analysed. A logistic regression analysis was conducted to evaluate the relationship between visual impairment and possible risk factors.

Results Eighty consecutive cases of paediatric bacterial keratitis cases were included, among which 59 were identified as having positive culture. *Staphylococcus epidermidis* was the most commonly isolated organism ($n = 23$; 39.0%), followed by *Streptococcus pneumoniae* ($n = 11$; 18.6%) and *Pseudomonas aeruginosa* ($n = 6$; 10.2%).

Antibiotic sensitivities revealed that tested bacteria had low resistance rates to fluoroquinolones and aminoglycosides (8.3–18.4% and 12.5–24.4%, respectively). Multivariate logistic regression analysis proved that visual impairment was significantly associated with Gram-negative bacterial infection (odds ratio (OR) = 7.626; $P = 0.043$) and an increasing number of resistant antibiotics (OR = 0.385; $P = 0.040$).

Conclusions *S. epidermidis* was the most common isolated organism in Shanghai paediatric keratitis. The fluoroquinolones and aminoglycosides remained good choices for treating these patients. Gram-negative

bacterial infection and an increasing number of resistant antibiotics were associated with worse visual prognoses in paediatric keratitis.

Keywords: bacterial keratitis; antibiotics; paediatrics; prognosis; susceptibility

Introduction

Paediatric bacterial keratitis is an uncommon but potentially devastating condition. The disease is particularly grave in children because they are at greater risk of developing irreversible ocular sequelae, most notably secondary amblyopia.¹ In addition, infectious inflammation in ocular surface appears to be more severe in paediatric patients, and usually they are more difficult in cooperating with ocular examination and topical medication.² Hence, empiric antibiotic treatment may be of utmost importance before culture results are available. However, most therapy regimens for paediatric bacterial keratitis are based on current guidelines for the treatment and management of this disease in adults.³ As a result, susceptibility testing should be performed periodically to ensure that the antimicrobials available are providing sufficient coverage against clinical isolates of pathogenic bacteria.

It is worth noting that despite the significant morbidity of paediatric bacterial keratitis, the incidence, pathogenesis, diagnosis, and predisposing factors of the disease in this patient group are not well known. So far, only a

few studies from the United States, India, and Taiwan have demonstrated its characteristics,^{1,4–8} with predisposing factors reported to be contact lens wear, trauma, ocular disease, systemic disease, and environmental factors.^{2,9,10} The purpose of this study was to review the microbiological profile and *in vitro* antibiotic susceptibility of paediatric bacterial keratitis diagnosed by our institution, and to explore their relationships with visual outcomes.

Materials and methods

Study population

A retrospective review of the clinical and microbiological records of Shanghai Eye, Ear, Nose, and Throat Hospital, China identified 80 bacterial keratitis cases among children aged ≤ 16 years from January 2005 to December 2010. The Medical Ethics Committee of our unit approved the study protocol before data collection. The research conducted met the tenets of Helsinki. Written consent was obtained from patients' parents. Patients who met the criteria of having corneal stromal infiltrate on slit-lamp examination and its microbiological evaluation for suspected microbial keratitis were included in this study, as shown in Supplementary Figure 1. Patients who were suspected of having bacterial keratitis based on their clinical findings and had undergone further microbiological evaluation were included in this study. Patients either suspected of having fungal, viral, or *acanthamoeba* infection based on clinical findings, or having a positive culture of these pathogens were excluded.

Microbiological analysis

All patients had initial corneal smears and cultures using a previously described technique.^{1,9} Sedation with intramuscular promethazine (2 mg/kg) was administered if required. Briefly, corneal scrapings obtained by a sterile Bard Parker blade were inoculated directly into a blood, chocolate, non-nutrient, Sabouraud's dextrose agar and potato dextrose agar, thioglycolate, and brain-heart infusion broth. Sabouraud's and potato dextrose agar plates were incubated at 25 °C to enhance the growth of fungi, and the remainder was incubated at 37 °C. Blood agar was incubated under both aerobic and anaerobic conditions, chocolate agar was incubated at 5% carbon dioxide and non-nutrient agar was incubated with an added *Escherichia coli* suspension. A culture was considered positive when there was growth of the same organism on two or more media, confluent growth at the site of inoculation on one solid medium, growth in one medium

with consistent direct microscopic findings or growth of the same organism on repeated corneal scraping. *In vitro* susceptibility was determined by Kirby–Bauer disk diffusion and E test (AB Biodisk, Piscataway, NJ, USA). Susceptibility testing of bacterial isolates was performed with fluoroquinolones (levofloxacin, ciprofloxacin, and ofloxacin), aminoglycosides (tobramycin, gentamicin, and amikacin), cephalosporins (cefepime, ceftazidime, and cefazolin), penicillin, and vancomycin.

Treatment

Against bacterial keratitis, levofloxacin (0.5%) hourly was the first line of therapy. If clinical response was unsatisfactory, antimicrobial therapy was changed either by adding tobramycin (0.3%) or as per culture and antibiotic susceptibility reports, if available.¹¹ Patients with any of the following conditions, including extremely thin cornea, impending or frank perforation, progressive or unresponsive disease, and endophthalmitis, underwent keratoplasty to remove the focal infection and restore visual acuity.

Visual outcome evaluation

The following data were collected from each patient: age, gender, bacterial isolates, number of resistant antibiotics, the duration of the symptoms before the first examination, ocular surface diseases (that is, previous herpetic infection, blepharitis, or other eyelid abnormalities), ocular surgery (corneal, cataract, or vitreous surgery), and ocular trauma. Different visual acuity tests were performed at 3 months after initiation of antibiotic therapy according to patients' age. In infants who were younger than 16 months, Fixation and Following Test was chosen; in toddlers with age between 16 months and 3 years, Hundred and Thousand Sweet Test was used; in those older than 3 years, if data were available, visual outcome was recorded using Snellen letter charts. In the present study, eyes with either negative result of Fixation and Following Test or Hundred and Thousand Sweet Test or best-corrected distance visual acuity worse than 6/60, were considered as visual impairment. Three patients with obvious corneal leukoma were also defined as visually impaired, although their visual acuity was not available.

Statistical analysis

Statistical analysis was performed using a statistical software package (SPSS for Windows, version 16.0; SPSS, Inc., Chicago, IL, USA). Data are shown as mean $\pm$ SD. For comparison, the data were grouped into two 3-year study periods, from January 2005 to December 2007 and

from January 2008 to December 2010. The percentage of bacterial isolates was analysed by χ^2 -test and Fisher's exact test. All variables of patients' data were entered into univariate analysis; variables with a probability of ≤ 0.2 for relationship with visual outcome were entered into multivariate logistic regression analysis. All *P* values were two-sided and considered statistically significant when < 0.05 .

Results

Demographics of patients

During the study period, 80 reports of paediatric bacterial keratitis with corneal cultures were received. The average age of all subjects was 6.6 ± 4.4 years (range, 0.2–16) and all patients were followed up for ≥ 3 months. A total of 59 bacterial pathogens were isolated from 59 eyes (73.8%), with 37 found in males (62.7%), and 22 in females (37.3%). None of them were visually impaired before the onset of disease, as reported by their parents.

Microbiological characteristics

The number of corneal cultures obtained and percentage of positive cultures remained relatively consistent between two 3-year study periods, as shown in Table 1. *Staphylococcus epidermidis* was the most commonly isolated organism ($n = 23$; 39.0%), followed by *Streptococcus pneumoniae* ($n = 11$; 18.6%) and *Pseudomonas aeruginosa* ($n = 6$; 10.2%).

Susceptibility testing of bacterial isolates is shown in Table 2. We analysed the effectiveness of commonly used empirical antibiotics in clinics, including fluoroquinolones, aminoglycosides, cephalosporins, penicillin, and vancomycin. More than 80% of tested Gram-positive isolates were susceptible to levofloxacin, ciprofloxacin, ofloxacin, amikacin, cefepime, ceftazidime, cefazolin, and vancomycin, whereas $< 70\%$ were sensitive to tobramycin, gentamicin, and penicillin. Less than 20% of Gram-negative isolates were shown to be resistant to various antibiotics except cefazolin and penicillin.

Multivariate logistic regression analysis for potential risk factors associated with visual impairment

Visual outcome of the affected eye at final follow-up is shown in Table 3, indicating that 35 eyes (59.3%) were considered to be visually impaired, including three uncooperative patients because of corneal leukoma. The data of these three patients were subjectively adjusted to facilitate multivariate logistic regression. Table 4 shows the clinical characteristics of paediatric bacterial keratitis cases and univariate analysis for their risk factors. As shown in Table 5 and Supplementary Table 1, two variables were finally proved to have significant association with visual impairment: Gram-negative bacterial infection (odds ratio (OR) = 7.626; $P = 0.043$) and an increasing number of resistant antibiotics (OR = 0.385; $P = 0.040$).

<i>Visual impairment^b</i>		
Yes	24	40.7
No	35	59.3
Total	59	100

^a As these three patients had obvious corneal leukoma, they were also defined as having visual impairment.^b Visually impairment was defined as Fixation and Following Test (–), Hundred and Thousand Sweet Test was (–), or best-corrected distance visual acuity was <6/60 at 3 months after initiation of antibiotic therapy.

Discussion

Bacterial keratitis occurs infrequently in children, who differ from adults in many aspects, including more difficulty in cooperating with examination and

treatment, greater inflammation severity and higher risk of amblyopia. Cases of paediatric bacterial keratitis have been reported in children with the age of 1 month and onwards by various authors.^{12,13} In the present study, bacterial keratitis was found to occur more frequently in boys than in girls. Kunimoto *et al*¹ did not identify unequal gender distribution in paediatric microbial keratitis cases, whereas Cruz *et al*⁵ have found a male preponderance.

The yield rate for corneal cultures in this study was 73.8%, which was significantly higher than previous reports from East Asia^{1,6} but similar to the North American and South Asia experience.^{5,7,14} The prevalence of pathogens causing paediatric bacterial keratitis varies among previous reports. Ormerod *et al*⁷ found that 92% of infections involved *P. aeruginosa* and/or various *streptococcus* species; later in childhood the typical adult pattern of infection was more common. Cruz *et al*⁵ revealed that *P. aeruginosa* and *Staphylococcus aureus* were the most common organisms isolated. Similarly to previous studies,^{1,6} in our series, *Staphylococcus* species and *S. pneumoniae* were the predominant Gram-positive micro-organisms and *P. aeruginosa* was the major Gram-negative micro-organism associated with bacterial keratitis in children. Geographical and climatic factors may partially explain the different prevalence rate. Notably, the role of *S. epidermidis* in the pathogenesis of bacterial keratitis is controversial and has not been clearly determined, because of its potential to contaminate an otherwise sterile corneal scraping and its controversial virulence.

In the 59 cases recruited, we did not find *Haemophilus influenzae*. There were two possible reasons for this

phenomenon. First, *H. influenzae* is a frequently isolated pathogen in the paediatric population in ocular surface infection, but mostly in acute bacterial conjunctivitis. The incidence of *H. influenzae* in paediatric keratitis was very low. Hsiao *et al*⁸ reported that 2 of 78 children with microbial keratitis in Taiwan were found to have *H. influenzae* infection. Keay *et al*¹⁵ revealed that only one case was found positive for this bacteria in 291 microbial keratitis patients.¹⁵ Also, according to the Preferred Practice Pattern published by American Academy

Ophthalmology, the incidence of *H. influenzae* in common causes of bacterial keratitis in the USA was only 2.5%. Second, the present study was performed in a tertiary eye care unit in Shanghai. We did not encounter the cases receiving effective treatment in primary or secondary hospital and therefore having no need for further referral. Caution should be taken in the interpretation of the results of this study.

To date, there is little information available about *in vitro* susceptibility patterns to antibiotics of paediatric

bacterial keratitis cases. Our study showed a better efficacy of fluoroquinolones than aminoglycosides in the treatment of bacterial keratitis, though both had acceptable susceptibility rates. Nowadays, the use of fluoroquinolones has gained popularity as an effective monotherapy for these patients.^{16–20} These agents provide coverage against most Gram-negative and Gram-positive bacteria, good ocular penetration, low toxicity, safety, and commercial availability.²¹ Hence, even though several cases of fluoroquinolone resistance have been published,^{18,22,23} our results show that, based on the susceptibility results for this geographic region, quinolones are still a good choice for paediatric bacterial keratitis in the Eastern China area, just as the susceptibility test in the current study showed. In addition, the first-generation cephalosporin, cefazolin, had a low level of antibacterial efficacy. However, the third-generation cephalosporins, cefepime and ceftazidime, had high activity against microorganisms involved in paediatric bacterial keratitis. Ceftazidime may be used as a fortified antibiotic in treating bacterial keratitis.

In our study, 24 eyes (40.7%) were considered to be visually impaired. Previous studies showed that 11.8–39.3% of childhood microbial keratitis, not just bacterial infection, had a visual outcome of worse than 6/60.^{2,7,8,24} Variations in the reported visual impairment rate may be because of the inclusion of patients with different severity and different pathogen. Relationships between the presence of visual impairment and clinical characteristics of paediatric patients were also explored in the present study, and Gram-negative bacterial infection and the increasing number of resistant antibiotics were found to be independent risk factors. Previous reports have addressed the risk factors predisposing patients to worse prognosis of bacterial keratitis. In the last century, infection caused by *P. aeruginosa* was most likely to result in a poor outcome.¹⁵ Ten years later, Miedziak *et al*²⁵ reported that older age, delay in referral to the corneal specialist, topical steroid treatment, past ocular surgery, poor vision at presentation, large size and central location of the ulcer were risk factors for poor outcome of microbial keratitis leading to penetrating keratoplasty. In 2003, Bourcier *et al*²⁶ revealed that 'very poor' visual outcome was significantly correlated with a history of ocular surface disease or systemic disease, diffuse infiltrate localised at the central or inferior cornea, severe anterior chamber inflammation, and depth of the infiltrate. In their series, there was no correlation between visual outcome and contact lens wear, history of corneal trauma or surgery, number of localisations, and type of bacteria. Recently, though, Keay *et al*²⁷ identified that ocular trauma and contact lens wear are the major predisposing

factors for microbial keratitis in adolescents and adults ranging from 15 to 64 years in age, and vision loss was proved to be only associated with clinical severity.

Interestingly, onset time proved to have significant correlation with visual impairment by multivariate logistic regression analysis (Table 5), which was different from univariate analysis (Table 4). In previous studies, longer delay between the onset of the symptoms and the first examination is thought to be an important indicator of prognosis.²⁶ However, logistic regression analysis using onset time and other variables, as shown in Supplementary Table 1, revealed that this phenomenon might be attributed to the bias induced by bacterial isolates infection. The disparity between previous studies and ours may have several reasons. First, previous studies were carried out in all ages or adults, while our cases were all children. Second, the patients enrolled may have different clinical severity, which would bias the results. Third, different statistical methods used may be another explanation. The simplicity of the univariate analysis has restricted its use because several factors can affect visual outcomes. Multivariate analysis can describe and be used for inference on a set of data even when several variables are involved, so its conclusion is more persuasive.

Several limitations of the present study should be noted. First, it is a retrospective study, and information of risk factors was only available when documented in the medical record. Some individuals may have additional risk factors that were not reported in their clinical record, such as the severity of corneal ulcers, including size, location, depth, and reaction. Second, similarly to previous studies, the present study was performed in a tertiary eye care unit in Shanghai, which may result in a potential selection bias. Third, *in vitro* susceptibilities were based on serum concentrations that may not be applicable to topically administered antibiotics, but these susceptibility patterns were still useful for guiding clinical judgment in antibiotic choice. Another limitation is that the presence of visual impairment was difficult to confirm in underage children. We have no alternative but to consider them as being visually impaired by the diagnosis of corneal leukoma.

In summary, among paediatric bacterial keratitis cases in our unit, *S. epidermidis*, *S. pneumoniae*, and *P. aeruginosa* were the most commonly isolated pathogens. The presence of visual impairment in paediatric patients was significantly associated with Gram-negative infection and the increasing number of resistant antibiotics. These findings may be important because they suggest that results of corneal culture and *in vitro* susceptibility are useful for indicating the prognosis of paediatric bacterial keratitis cases.

Summary

What was known before

- Only a few studies from the United States, India, and Taiwan have reported the characteristics of paediatric bacterial keratitis in children.
- To date, there is little information available about *in vitro* susceptibility patterns to antibiotics of paediatric bacterial keratitis cases.
- Relationships between presence of visual impairment and clinical characteristics of paediatric patients were explored by univariate analysis.

What this study adds

- This study provided the microbiological profile, *in vitro* antibiotic susceptibility, and visual outcomes of paediatric microbial keratitis in China for the first time.
- *S. epidermidis* was the most common bacterial keratitis isolate in children in Shanghai. The fluoroquinolones and aminoglycosides remained good choices for treating these patients.
- By multivariate logistic regression analysis, we found that Gram-negative bacterial infection and increasing number of resistant antibiotics may predict worse visual outcome.
