Dissection of complex traits that influence fitness is not only a central topic in evolutionary research but can also assist breeding practices for economically important plant species, such as loblolly pine (*Pinus taeda* L.). In this study, 46 single nucleotide polymorphisms (SNPs) from 41 disease and abiotic stress-inducible genes were tested for their genetic association with carbon isotope discrimination (CID), a time-integrated trait measure of stomatal conductance. A family-based approach to detect genotype/phenotype genetic association was developed for the first time in plants by applying the quantitative transmission disequilibrium test on an association population of 961 clones from 61 families (adopted from previous breeding programs) evaluated for phenotypic expression of CID at two sites. Two particularly

promising candidates for their genetic effects on CID are: *dhn-1*, involved in stabilization of cell structures, and *lp5-like*, a glycine rich protein putatively related to cell wall reinforcement proteins, both of which were shown in previous studies to be water-deficit inducible. Moreover, association in *lp5-like* involves a nonsynonymous mutation in linkage disequilibrium with two other nonsynonymous polymorphisms that could, by acting together, enhance overall phenotypic effects. This study highlights the complexity of dissecting CID traits and provides insights for designing second-generation association studies based on candidate gene approaches in forest trees.

Heredity (2008) 101, 19–26; doi:10.1038/hdy.2008.21; published online 14 May 2008

Keywords: association genetics; candidate genes; carbon isotope discrimination; *Pinus taeda*; single nucleotide polymorphisms; water use efficiency

Introduction

Candidate gene association studies aim at linking phenotypic variation with allelic variation in candidate genes and benefit from several generations of recombination in natural populations to identify causative polymorphisms (reviewed in Cardon and Bell, 2001; Gupta *et al.*, 2005; Hirschhorn and Daly, 2005; Laird and Lange, 2006; see Neale and Savolainen, 2004 for conifers). In plants, association studies have been relatively successful, but only a limited number of genes and traits have been tested for association to date. In forest trees, only two studies are available: Thumma *et al.* (2005) identified allelic variation in *cinnamoyl CoA reductase* affecting microfibril angle, a wood quality trait, in Eucalyptus and González-Martínez *et al.* (2007) found four genes (*cad*, *sams-2*, *lp3-1* and α -*tubulin*) associated with different wood property traits in *Pinus taeda*. Most genetic association studies so far have targeted major commercial traits (wood property traits in commercial forest trees, Thumma *et al.*, 2005; González-Martínez *et al.*, 2007; kernel composition, starch properties and

forage digestibility in maize, Guillet-Claude *et al.*, 2004; Wilson *et al.*, 2004) or focused on well-known pathogen resistance or flowering time genes (Thornberry *et al.*, 2001; Aranzana *et al.*, 2005; see also Zhao *et al.*, 2007). Addressing traits of a higher complexity, such as those drought related, may pose additional difficulties.

All previous examples of association studies in plants have, without exception, focused on natural populations. In contrast, association studies on other organisms such as humans and cattle have normally used family-based populations (Hirschhorn and Daly, 2005; Laird and Lange, 2006). Family-based designs in association studies might incorporate advantages of both linkage-based and linkage disequilibrium-based quantitative trait dissection approaches (for example, the transmission disequilibrium test (TDT) and its multiple extensions; Spielman *et al.*, 1993; see review in Laird and Lange, 2006). Families might be generated through controlled crosses among a diverse selection of unrelated individuals according to a breeding scheme that aims at shuffling of alleles in multiple samples either across backgrounds or against a reference background, thus enhancing the level of linkage disequilibrium (LD) observed in the parents (Yu *et al.*, 2006). The subsequent generations of progeny of the crosses can then be used as association populations (reviewed in Ersoz *et al.*, 2007).

Admixture and stratification are known biases in genetic association studies and a major cause of false-positives in classic studies based on natural populations

(see, for instance, Hirschhorn and Daly, 2005; Figure 3). However, attempted corrections of false positives produced by population structure can result in removing true-positives, that is, causative polymorphisms that are removed because they are strongly correlated with population structure. For example, Zhao *et al.* (2007) noted that correcting false positives produced by population structure in *Arabidopsis* removed many of the best candidates for extreme late-flowering phenotypes of northern accessions (northern Sweden and Finland), which were genetically different from the others. Indeed, any polymorphism shared by these accessions and giving positive association with a flowering-time phenotype would be considered a false positive due to the misleading effect of population structure. In contrast to methods for association based on natural populations, family-based methods are robust against population admixture and stratification. Despite their obvious advantages, standard TDTs, such as quantitative TDT (QTDT) (Abecasis *et al.*, 2000a,b), require individuals to have heterozygous ancestors in the pedigree to be informative and might have lower power than classic natural population-based association studies.

The response of plants to dehydration is complex and involves numerous biochemical, physiological and morphological alterations to reduce water loss and protect cells from desiccation (reviewed in Ingram and Bartels, 1996; Shinozaki and Yamaguchi-Shinozaki, 2007). Abiotic stress-inducible genes include: (i) signaling cascades (Dubos and Plomion, 2003), (ii) transcription factors, either ABA-independent (for example, DREB2, Riera *et al.*, 2005; Agarwal *et al.*, 2006) or ABA-dependent (for example, MYB, Cominelli *et al.*, 2005; Riera *et al.*, 2005); (iii) protection factors of macromolecules (for example, dehydrins and chaperones, Close, 1997; Ismail *et al.*, 1999; Rorat, 2006); (iv) detoxification enzymes (for example, antioxidants, Karpinska *et al.*, 2001; Reddy *et al.*, 2004) and (v) water channels and transporters (for example, aquaporins, Luu and Maurel, 2005; Kiani *et al.*, 2007). In natural populations of forest trees, some of these genes are likely adaptive (for example, *ccoamt-1* and *erd3* in *Pinus taeda*, González-Martínez *et al.*, 2006; *pr-agp4*, *erd3*, *dhn-1*, *dhn2* and *lp3-1* in *Pinus pinaster*, Eveno *et al.*, 2008). Remarkably, gene expression of drought-induced genes can vary even in populations located in close geographic proximity (Sathyan *et al.*, 2005), which might reflect different adaptations to drought tolerance, as it has already been shown for physiological traits in experimental conditions (for example, Nguyen-Queyrens and Bouchet-Lannat, 2003).

The complexity of drought-response in plants also poses difficulties for measuring drought-related traits. Several parameters related to the hydraulic properties of trees have been suggested, such as leaf-to-wood area ratios, leaf hydraulic conductivity, vulnerability to xylem embolism, carbon isotope discrimination (CID) of needles/leaves or wood (that is, the ratio between stomatal conductance and photosynthetic capacity; Farquhar *et al.*, 1989) and different water potentials (reviewed in Martínez-Vilalta *et al.*, 2004 for Pinaceae). Among all these methods, CID (Δ) has been favored in recent years because of its amenability to high-throughput phenotyping and its putative correlation with other hydraulic parameters, at least in Pinaceae (Martínez-Vilalta *et al.*, 2004 and references therein). Furthermore, genetic

studies from model organisms such as *Arabidopsis* indicated that CID might have higher heritability in C3 plants than other measures of WUE (McKay *et al.*, 2003). Nevertheless, CID is a complex trait that can also vary substantially with environmental variables, such as altitude (see, for example, Warren *et al.*, 2001) or CO₂ concentration (Tjoelker *et al.*, 1998). Warren *et al.* (2001) also found that CID was notably affected by both fertilization levels and stand density in *Pinus radiata* and *P. pinaster*. Therefore, care must be taken when interpreting CID results in terms of drought tolerance (see also Baltunis *et al.*, 2008).

Testing and improving tree breeding stocks for enhanced drought tolerance and increased water use efficiency (WUE) have become major objectives in commercial production, especially considering recent (and future) global climate changes. Dissecting the molecular basis of drought tolerance in plants also has relevant implications for conservation genetics and evolutionary research. In this paper, 46 single nucleotide polymorphisms (SNPs) from 41 disease and abiotic stress-inducible genes, previously screened for their patterns of nucleotide diversity and LD (Brown *et al.*, 2004; Ersoz, 2006; González-Martínez *et al.*, 2006), were tested for association with CID, a trait related to WUE and potentially to drought, in forest trees.

Materials and methods

Plant material and trait measurements

Sixty-one families were generated using a partial diallel mating design as part of the Forest Biology Research Cooperative (FBRC) Tree Improvement Program (University of Florida, Gainesville, FL, USA), using 31 diverse natural selections (Figure 1) from three provenances (Atlantic Coastal Plain, Florida and Gulf Coast) that were previously analyzed for their nucleotide diversity and LD levels (Brown *et al.*, 2004; Ersoz, 2006; González-Martínez *et al.*, 2006). Family size varied from 15 to 18 clones, with an average of 16. Propagules were allocated to replications according to an incomplete block design with 12–16 trees per incomplete block, in each of two sites (Cuthbert, Georgia and Palatka, Florida). Full common garden design description and details on isotope ratio measurements are given in Baltunis *et al.* (2007, 2008). Measurements were repeatable and accurate with a standard error of 0.14‰. CID values (Δ) were calculated from $\delta^{13}\text{C}$ values using Equation (1) (Farquhar *et al.*, 1989):

$$\Delta = \frac{\delta_a - \delta_p}{1 + \delta_p} \quad (1)$$

where δ_p is the isotope composition of the plant material and δ_a is that of the air (assumed to be -8‰).

Mean discrimination at the Georgia and Florida sites was 21.2 and 19.6‰, respectively. Provenance and family effects were significant, CID being slightly more heritable at Cuthbert than Palatka, with narrow-sense heritability (h^2) estimates of 0.20 and 0.14, respectively, and an across-site estimate of 0.09 (Baltunis *et al.*, 2008). Correlation across sites was only moderate, probably due to environmental differences between sites and genotype per environment ($G \times E$) interactions. $G \times E$ interactions and the contrasting architecture of the

Figure 1 Origin of parental first-generation selections and location of study sites (stars). Size of dots is proportional to the number of trees sampled at that location. Minimum temperature isotherms indicating zones recommended for seed transfer are also shown (see Schmidting, 2001). The shadowed pattern represents the native range of *P. taeda* in southeastern United States.

nonadditive genetic variance at Cuthbert and Palatka sites (due to epistasis and dominance, respectively; see Baltunis *et al.*, 2008) argue in favor of treating CID in the two sites as different traits. A linear model was used to generate best linear unbiased predictions for each single site as follows:

$$y_{ijkl} = \mu + A + B + C + r_i + gca_j + gca_k + sca_{jk} + c(fam)_{jkl} + rgca_{ij} + rgca_{ik} + rsca_{ijk} + e_{ijkl} \quad (2)$$

where μ is the overall mean; A , B and C are regressors with values equal to 0, 0.5 or 1 depending on whether the parents for a given family belongs to the same provenance (for example, $A = 1$, $B = 0$, $C = 0$) or not (for example, $A = 0.5$, $B = 0.5$, $C = 0$), thus representing the provenance effect; r_i is the i -th repetition; gca_j and gca_k are the general combining ability of the j -th female and the k -th male, respectively; sca_{jk} is the specific combining ability of the j -th female with the k -th male; $c(fam)_{jkl}$ is the l -th clone within the jk -th family and e_{ijkl} is the error term. The r_i , gca_j , gca_k , sca_{jk} and $c(fam)_{jkl}$ are treated as random variables. Clone best linear unbiased predictions for genotype/phenotype genetic association were generated by summing the provenance estimates and the gca_j , gca_k , sca_{jk} and clone within family, $c(fam)_{jkl}$, predictions. Analyses were performed using SAS 9.0 and ASReml statistical packages.

DNA isolation and SNP genotyping

DNA isolation was performed by grinding needle tissue in liquid nitrogen followed by whole DNA extraction using the QIAGEN DNeasy Maxi plant DNA extraction kit (Valencia, CA, USA). A total of ~5–10 ng of DNA was used for down stream PCR applications. Genotyping was conducted on a Victor²-Wallac SNP genotyping platform with the AcycloPrime Universal Fluorescence Polarization Terminator Dye Incorporation kit (FP-TDI, Perkin-Elmer, Torrance, CA, USA; see Kwok, 2002, for a

description of the method). PCR reactions were conducted following the manufacturer's AcycloPrime FP-TDI assay protocols and adjusting dNTPs (200–800 μ M) and primers (200–800 nM) concentration and number of PCR cycles (15–35). Sequences for the genotyping primers, their annealing temperatures, direction of single-nucleotide extension reaction, minor allele frequency (MAF) and the alleles at the SNP loci are listed in Supplementary Table S1. A total of 46 SNPs were genotyped in 961 clones from 61 families, resulting in ~44 206 data points, with ~10% missing data.

Genetic association methods

Several family-based methods have been developed in the last decade, starting with the original formulation of the TDT by Spielman *et al.* (1993). Here, the orthogonal model of Abecasis *et al.* (2000a,b) was used for data analysis (see also Fulker *et al.*, 1999). This extension of the TDT for quantitative traits, the QTDT, is based on the difference between average phenotypic values of individuals with different alleles transmitted from a heterozygous parent, computed using standard variance-component methods and the identity by descent among relatives. The QTDT is robust to population stratification and admixture. First, for a bi-allelic marker M with arbitrarily named alleles A and B , we define the genotype score g_{ij} for the j -th offspring in the i -th family as the number of ' A ' alleles at locus M minus one. Second, the genotype score (g_{ij}) is decomposed into two orthogonal components: the between-family component b_i and the within-family component $w_{ij} = g_{ij} - b_i$. In this formulation, b_i represents the average within-family genotype that in our study case is obtained from sib information as follows:

$$b_i = \frac{\sum_k^{\text{sibship}} g_{ik}}{n_{\text{sibs}}} \quad (3)$$

Then, the means model under this specification is:

$$Y_{ij} = \mu + \beta_b b_i + \beta_w w_{ij} \quad (4)$$

where μ is the overall mean; b_i and w_{ij} are the orthogonal between- and within-family components of g_{ij} ; and β_b and β_w are regressors. Within-family tests of association are developed by comparing quantitative models, including only the between-family component (null model) or both within- and between-family components (full model), using likelihood ratio tests that assume a normal distribution for the traits. In the absence of population structure, total association confers more power and makes detection of correlation between a marker and an underlying trait easier than within-family association. Therefore, we also tested for total association, using both within-family and between-family components, in the cases where no evidence of population stratification was observed ($\beta_b = \beta_w$). Finally, a Monte-Carlo permutation framework was used to compute unbiased P -values. This permutation scheme corrects for small sample sizes, ascertainment bias and, most importantly, for deviations from normality of phenotypic variables. Similar results to the orthogonal model were obtained using the Monks *et al.* (1998) model and are thus not presented here. Analyses were done using QTDT software (available at www.sph.umich.edu/csg/abecasis/QTDT/; January 2008).

When significant genetic association was observed, the approximate phenotypic variation explained by the marker was calculated as:

$$2p(1-p)a^2/V_p \quad (5)$$

where V_p is the total phenotypic variance, p is the marker allele frequency and a is the additive effect, which is estimated by the β_w regression coefficient (Fulker *et al.*, 1999; Abecasis *et al.*, 2000a).

Data perturbation simulations

Following Yu *et al.* (2006) and Zhao *et al.* (2007), a simulation scheme based on the perturbation of existing phenotypes was implemented. The method consisted in the addition of a constant additive effect to the minor allele of a randomly chosen causal SNP, while keeping the real data structure. Allelic fixed effects ranging from 0.1 to 0.5 times the standard deviation of the phenotype (accounting for SNP effects on phenotype of ~0.5–10%) were considered. Simulations were used to compare the power of QTDT and the family-based design used here

with an unstructured population of the same size ($N=961$), generated from the sibs allele frequencies and tested for association using standard general linear models. Power estimates were computed separately for different MAF classes ($MAF < 0.1$, $0.1 \leq MAF < 0.2$ and $MAF \geq 0.2$).

Results

Quantitative transmission disequilibrium test was used to obtain evidence for association between SNP alleles in 41 candidate gene loci to CID phenotypes at two field trials in which the association population was grown. CID was heritable at both sites ($H^2 = 0.33$ at Cuthbert, GA and 0.25 at Palatka, FL; Baltunis *et al.*, 2008). Analyses for within-family genetic association were based on an average of 415 and 495 probands (that is, sibs with heterozygous parents) in Cuthbert and Palatka, respectively. In general, SNPs giving genetic association at the within-family level were also significant or nearly significant for total association (only SNPs that did not show population structure were tested for total association; see Table 1).

Significant genetic association was found between CID phenotypes measured at Cuthbert and the silent SNP Q1 in 44 segregating families within the *dehydrin 1* (*dhn-1*) locus. At the Palatka site, significant genetic association was found for C13 in 26 segregating families; C13 is a nonsynonymous polymorphism in a putative cell wall protein similar to *lp5* in *Pinus taeda*. Another two (silent) SNPs were significantly associated with CID phenotypes: C22 (18 segregating families) from a *wrky-like* transcription factor and S9 (32 segregating families) from *Cu/Zn superoxide dismutase* (*sod-chl*) gene at Cuthbert and Palatka, respectively, but supporting evidence for genotype/phenotype associations was weaker (Table 1). No significant associations between candidate SNPs and CID phenotypes were detected simultaneously at both sites. This is consistent with the moderate genetic correlation for the CID trait across sites, which indicates rank changes in the expression of the CID phenotype by clones at the two sites. Thus, we did not necessarily expect identical associations to be detected for both sites in this analysis.

None of these associations were significant after correcting for multiple testing (Bonferroni threshold for

Table 1 Genetic association between 46 SNPs from 41 disease and abiotic stress-inducible genes and carbon isotope discrimination in two sites (Cuthbert and Palatka)

SNP	Gene	Cuthbert			Palatka		
		MAF	Within-family ^a	Total	MAF	Within-family ^a	Total

C13	Putative cell wall protein, similar to <i>lp5</i> in <i>Pinus taeda</i>	0.11	NS	NS	0.11	0.015 (0.60%)	0.018
S9	<i>Cu/Zn superoxide dismutase</i> , nuclear gene for chloroplast product	0.16	0.087	PS	0.16	0.049 (0.97%)	0.086
C22	<i>wrky-like</i> transcription factor	0.46	0.035 (3.38%)	0.055	0.47	NS	NS

Abbreviations: MAF, minor allele frequency; NS, not significant; PS, locus showing population structure; SNP, single nucleotide polymorphisms.

Only associations with P -values lower than 0.05 for any tests are given; values with $P < 0.05$ are given in bold and the percentage of phenotypic variance explained (within-family test) are given in parentheses. Within-family association compares a quantitative model including only the between-family component (null hypothesis) with a full model including also the within-family component, whereas total association does not consider population structure ($\beta_b = \beta_w$; see details in the text). Only SNPs that were not significant in population stratification tests were included in total association analyses.

^a P -values computed by permutation (1000 permutations).

Figure 2 Power (as estimated by P -values achieved) of the family-based design used here (dark lines) in comparison with an unstructured population of the same size ($N = 961$), generated from sibs allele frequencies (light lines) and tested for association using standard general linear models (GLMs). Estimates are presented separately for different minor allele frequency (MAF) classes ($MAF < 0.1$, $0.1 \leq MAF < 0.2$ and $MAF \geq 0.2$).

$P < 0.05$ was 0.001) and the allelic effect on the phenotype was lower than 1% in all cases, except one (C22, which explained 3.38% of the phenotypic variance), as roughly estimated by (S). Weak associations ($0.5 < P \leq 0.10$) were detected for *chromatin assembly transcription factor 1* (*caf-1*), *caffeoyl-CoA-O-methyltransferase 1* (*ccoaomt-1*), *ethylene insensitive 2* (*eins-2*) and another *wrky* class transcription factor (Supplementary Table S2). Finally, (more powerful) tests of total association but not within-family tests pointed out tentative genetic association for a *terpene synthase-like* (*tps-like*) gene in Cuthbert and a *myb* class transcription factor in Palatka (see Supplementary Table S2).

Simple simulations showed a reasonably high power to detect association of QTDT with the present family-based experimental design given frequent SNPs ($MAF \geq 0.2$) and allelic effects of ~ 0.1 times the phenotypic standard deviation (equivalent to $\sim 1\%$ of explained phenotypic variance per SNP) (Figure 2). However, to reach significance levels after correction for multiple testing (Bonferroni threshold for $P < 0.05$ was 0.001), higher allelic effects, of the order of $\sim 2.5\%$ of explained phenotypic variance per SNP, were needed. Power to detect association decayed rapidly for low frequency ($0.1 \leq MAF < 0.2$) and rare alleles ($MAF < 0.1$) (see Figure 2). In comparison with an equivalent design based on unstructured populations (and analyzed using standard general linear models), QTDT and the family-based design used in this study achieved less power in all scenarios. Differences between methods were especially notable when low frequency and rare alleles were considered.

Discussion

Response to and recovery from drought is a complex process that involves multiple biochemical, physiological and morphological adaptations in plants. Pines are particularly vulnerable to xylem embolism (reviewed in

Martínez-Vilalta et al., 2004) and have developed multiple mechanisms both to avoid and to tolerate drought, which are commonly recognized (see, for instance, Table 1 in Newton et al., 1991). In this study, positive genetic association between a number of drought-inducible candidate genes and CID in needles was found. The CID, applied to different plant tissues (generally needles or leaves but also wood), is a time-integrated estimator of photosynthetic WUE, that is, the ratio between net CO_2 assimilation and stomatal conductance, and has been extensively used to compare response to drought in plants, including forest trees (reviewed in Warren et al., 2001; Dawson et al., 2002; Adams and Kolb, 2004; Monclus et al., 2006).

High variation in CID has been found across species (for example, Oliveras et al., 2003 for conifers; Cernusak et al., 2007 for tropical trees), as well as moderate narrow-sense (h^2) heritability within-species (0.17 in maritime pine, Brendel et al., 2002; 0.09 across-sites in loblolly pine, Baltunis et al., 2008). As trees with higher WUE may sustain growth under water-limitation conditions and differences in WUE represent also different growing strategies, CID is an attractive trait for breeding, in particular in dry areas or in those regions in which the higher impact of the current process of global climate change will be felt.

Genotype/phenotype associations involve four genes belonging to different functional classes related to drought: general protection factors (*dhn-1*), antioxidants (*sod-chl*), transcription factors (*wrky-like*) and putative cell-wall proteins (*lp5-like*). Dehydrins are accumulated in vegetative tissues in response to cell dehydration and multiple protection-related functions have been described in numerous organisms for this widespread gene family (for example, stabilization of vesicles or other endomembrane structures, metal-binding activity, protection from oxidative damage, cryoprotective activity, and so on; see reviews in Close, 1997; Allagulova et al., 2003; Rorat, 2006). Dehydrins can be classified in structural types, probably related to distinct functions (Rorat, 2006), attending to the number and order of different domains (named the Y, S and K segments; see details in Close, 1997). *Dhn-1* showed 85% similarity to *PgDhn-1* from *Picea glauca*, a SK_n-type dehydrin that is overexpressed under wounding, cold and drought stress (Richard et al., 2000). SK_n dehydrins have been suggested to be involved in cold acclimation (Rorat, 2006 and references therein), metal detoxification (Zhang et al., 2006) and other abiotic-stress responses (Zhang et al., 2007).

Another candidate gene giving positive association with CID was a transcription factor, related to the WRKY family (that is, transcription factors that contain a DNA-binding region comprising the conserved sequence motif WRKY adjacent to a zinc-finger motif). Although little is known about this transcription factor family, their members seem to be upregulated by wounding, pathogen infection and diverse abiotic stresses, such as cold or drought (see reviews in Eulgem et al., 2000; Ülker and Somssich, 2004). Interestingly, the WRKY transcription factor family is involved in defense-induced mitogen-activated protein kinase signaling cascades (Asai et al., 2002) and in leaf senescence (Robatzek and Somssich, 2002) in *Arabidopsis*. The only candidate gene showing genetic association in both common garden experiments

Figure 3 Putative cell-wall protein *lp5*-like: (a) protein alignment with *P. taeda*'s *lp5* (AAB66348; reference sequence on top) highlighting nonsynonymous polymorphisms (including C13, S→R); (b) linkage disequilibrium plot (D' and r^2 are shown in the upper and lower parts of the plot, respectively, as obtained from Tassel software) for nonsynonymous single nucleotide polymorphisms, showing total and partial linkage of C13 with other nonsynonymous mutations close to the beginning of the coding sequence and (c) expressional profile obtained from *in silico* analysis using the Magic Gene Discovery tool (Laboratory for Genomics and Bioinformatics, University of Georgia; www.funngen.org); the pie graph represents the percentage of *lp5*-like ESTs (expressed sequence tags) found in root cDNA libraries from pines submitted to different stress treatments (nutrient deficiency, dark and abiotic stress) and in control libraries built with nonstressed pines (see further details in Lorenz *et al.*, 2006).

(albeit only marginally in the Cuthbert trial) was *sod-chl*, a Cu/Zn superoxide dismutase gene. At the Palatka site, CID of CT genotypes at *sod-chl* S9 was higher than TT genotypes in 70% of the families, with a mean within-family difference of 0.0551, while at the Cuthbert site the average difference between genotypes was around half this value (0.0298 with higher CID for CT in 63% of the families). Antioxidant activity increases after drought stress-induced generation of active oxygen species, which attack sensitive macromolecules resulting, ultimately, in cell death. Superoxide dismutases, in particular, are key players in the antioxidant defense system of most organisms, including humans (see, for instance, Wang *et al.*, 2003; Reddy *et al.*, 2004). The only significant genetic association involving a nonsynonymous polymorphism (C13) was found in a putative cell wall protein, similar to *lp5* in *Pinus taeda* (Figure 3a; see Chang *et al.*, 1996 for a description of *lp5* gene), which also has a 48.92% similarity with a glycine-rich protein in *Arabidopsis* (accession number O65450). Glycine-rich proteins are often associated with stress response in plants (reviewed in Mousavi and Hotta, 2005), as it may also be the case for *lp5* (see expressional profile in Figure 3c). Nonsynonymous SNP C13 (highlighted in Figure 3b) is in LD with two other nonsynonymous

mutations (not tested for association in this study) located toward the 5' end of the coding region. Multiple nonsynonymous mutations acting together (through LD) in the same direction may have higher phenotypic effects than single mutations.

The associations between CID and drought-inducible genes could be interpreted as reflecting adaptation to water-limiting conditions. However, water was probably not limiting for growth at either of the two loblolly pine testing sites, as indicated by a high water table at the time during which sampled leaves developed at the Palatka site and the positive correlations between growth and CID across both sites (Baltunis *et al.*, 2008). Thus, associations might be generated through differences in photosynthetic capacity, for example, through protection of the photosynthetic apparatus by dehydrins, during transient periods of water deficit that might occur in foliage during peak temperatures. Alternatively, the associations may be driven by the action of genes in LD with the detected polymorphism. Further analysis with a much larger set of candidate genes will answer this question. In addition, validation of significant associations between CID and candidate genes in other association populations tested in stressed and non-stressed environments will be required to establish a

more meaningful biological relationship between CID and drought-responsive genes.

None of the significant associations found in this study explained a substantial amount of the phenotypic variance present in the CID trait (<1% in all cases except C22) and only slightly higher values have been reported in other tree association studies, even for well-known traits such as those related to wood properties (Thumma *et al.*, 2005; González-Martínez *et al.*, 2007). This fact may indicate genetic control by many loci with relatively small individual effects and probably complex gene interactions. In addition, generally low phenotypic effects of single genes might explain the lack of significant association between CID phenotypes and some of the most promising drought-tolerance candidate genes tested in this study (such as *dhn-2* or *erd3*).

This study highlights the complexity of WUE in trees and provides insights for designing second-generation association studies for drought tolerance. First, CID, a commonly measured trait related to WUE, showed a remarkable environmental influence. This fact argues in favor of strict environmental controls and testing in a wide range of environments and water-deficit conditions. Second, genetic associations at Cuthbert and Palatka sites involved different functional candidate gene types, highlighting the multiplicity of drought response mechanisms in plants and the complexity of composite traits such as CID. This complexity, as compared with relatively simple and well-known metabolic pathways (for example, the lignification pathway, see Peter and Neale, 2004) and traits, might complicate validation of genotype/phenotype associations for WUE in future studies. It also argues for a wide sampling of the genome to cover a variety of processes, such as: water channeling, signaling cascades, radical scavenging, macromolecules and membranes stabilization, and so on. Finally, given the low variance explained by most associations (<5%, see also González-Martínez *et al.*, 2006) and the relatively poor performance of QTDI shown in our power simulations, future association studies should consider larger sample sizes, of the order of thousands of individuals, a much larger number of candidate gene loci and more powerful designs.

Acknowledgements

We thank Ricardo Alía for valuable comments and discussions and PC Grant for English language suggestions. Robert J Kuntz and Julie Beal provided technical assistance in the laboratory. The study of SC González-Martínez was supported by a Fulbright/MECD scholarship at the University of California (Davis) and the 'Ramón y Cajal' fellowship RC02-2941 (Spanish Ministry of Science). This research was supported by the ADEPT (Allele Discovery for Genes Controlling Economic Traits in Loblolly Pine) project funded in the framework of the Initiative for Future Agriculture and Food Systems (USDA, USA).
