ORIGINAL ARTICLE

Spatial organization of intestinal microbiota in the mouse ascending colon

Gerardo M Nava, Hans J Friedrichsen and Thaddeus S Stappenbeck

Department of Pathology and Immunology, Washington University School of Medicine, St Louis, MO, USA

Complex microbial populations are organized in relation to their environment. In the intestine, the inner lining (mucosa) is a potential focal point for such organization. The proximal murine colon contains mucosal folds that are known to be associated with morphologically distinct microbes. To identify these microbes, we used the technique of laser capture microdissection (LCM) to sample microbes associated with these folds (interfold region) and within the central lumen (digesta region). Using 16S rRNA gene tag pyrosequencing, we found that microbes in the interfold region were highly enriched for the phylum Firmicutes and, more specifically, for the families Lachnospiraceae and Ruminococcaceae. Other families such as Bacteroidaceae, Enterococcaceae and Lactobacillaceae were all enriched in the digesta region. This high-resolution system to capture and examine spatial organization of intestinal microbes should facilitate microbial analysis in other mouse models, furthering our understanding of host–microbial interactions.

Subject Category: microbe–microbe and microbe–host interactions

Keywords: intestine; Lachnospiraceae; microbiota; mucosa associated; pyrosequencing; spatial organization

Introduction

The intestinal mucosa is a complex and dynamic system that functions as a semipermeable barrier allowing the absorption of nutrients and macromolecules required for growth and development, while protecting the blood stream from potentially invasive microorganisms (Walker *et al.*, 1975a, b; Walker 1979). These basic functions are carried out in an environment inhabited by billions of commensal microbes from the three domains of life, Bacteria, Archaea and Eukarya (Eckburg *et al.*, 2005; Gill *et al.*, 2006; Scanlan and Marchesi, 2008), as well as by viral particles (Zhang *et al.*, 2006; Breitbart *et al.*, 2008).

Advances in molecular techniques have improved our understanding of intestinal microbiota. Comprehensive 16S rRNA gene clone libraries derived from biopsies, luminal contents and feces have shown that the intestinal microbiota of mouse and humans consists of hundreds of different phylogenetic species that can be classified into only four major microbial phyla: Firmicutes, Bacteroidetes, Proteobacteria and Actinobacteria, comprising 98% of the intestinal microbiota (Backhed *et al.*, 2005; Eckburg

et al., 2005; Ley *et al.*, 2005, 2006; Gill *et al.*, 2006; Frank *et al.*, 2007; Rajilic-Stojanovic *et al.*, 2007; Tap *et al.*, 2009).

Microbes are not randomly distributed in the environment. Microbial ecology studies (that is, soil environment) have shown that microbes exhibit spatially predictable and aggregated patterns from local to regional scales (Green *et al.*, 2004). In the intestine, one potential organizing factor is the mucosa, which forms a direct interface with the lumen. Interestingly, morphological studies of the intestinal lumen have shown that distinctive microbial populations are found near the mucosa of mice and man (Dubos *et al.*, 1965; Savage *et al.*, 1968, 1971; Savage, 1970; Savage and Blumershteyn, 1974). Later studies of 16S rRNA gene profiles showed that microbial populations associated with the intestinal mucosa are distinct from those found in fecal samples (Eckburg *et al.*, 2005; Zoetendal *et al.*, 2006). However, a typical limitation of these studies is that the overall structure of luminal microbes is disturbed during sample collection, thus potentially limiting the complete characterization of microbes that inhabit this location.

We used a combination of techniques that permitted the capture of intestinal microbes from specified regions of the mouse colonic lumen. First, highly penetrant organic fixatives were used to maintain the structure of the luminal contents throughout the entire sample preparation (Swidsinski *et al.*, 2005). Second, laser capture microdissection (LCM) was used to specifically

sample microbes that were either located near or distant to the mucosal surface. To best demonstrate the difference between these two populations, we focused on the ascending colon that is known to contain a morphologically distinct population of unidentified, large fusiform bacteria (Dubos *et al.*, 1965; Savage *et al.*, 1968, 1971; Savage, 1970; Savage and Blumershteyn, 1974). We found that these microbes were concentrated in areas between the mucosal folds (referred to herein as the interfold region). We also found that the corresponding region of the central lumen (referred to herein as digesta region) of the mouse ascending colon did not contain an obvious population of these fusiform bacteria. We collected microbial populations from these two regions by LCM, and characterized them by tag pyrosequencing and Sanger sequencing of 16S rRNA genes. This screen showed that Firmicutes were enriched in the interfold region, with Lachnospiraceae and Ruminococcaceae being the predominant families. This finding was confirmed by quantitative PCR (qPCR) and fingerprinting methods, showing no significant variation among mice. We propose that this technique will be useful in examining the microbial spatial organization in other intestinal locations in genetically and environmentally defined mouse strains.

Materials and methods

Mice

All animal experiments were conducted in accordance with approved protocols from the Washington University School of Medicine Animal Studies Committee. Adult (8–12 weeks old) wild-type C57/BL6 mice were housed in microisolator cages in a specified pathogen-free barrier facility following a 12-h light cycle and fed a standard irradiated chow diet (PicoLab Rodent Chow 20, Purina Mills, St Louis, MO, USA) and water *ad libitum*. A detailed description of the experimental design is shown in Supplementary Figure 1.

Tissue sampled

For all analyses, entire colons (from the ascending colon to the ano–rectal junction) were removed and immediately fixed by submersion in methacarn (60% methanol, 30% chloroform and 10% acetic acid; Uneyama *et al.*, 2002) for 15 min at 24 °C. Methacarn fixation fixative is an effective and conventional method to preserve the structure of the luminal contents and to examine the spatial organization of the intestinal lumens, including microbes and mucins (Matsuo *et al.*, 1997; Kikuchi *et al.*, 2005; Swidsinski *et al.*, 2005, 2007b). The fixed colons, including their luminal contents, were cut into serial 3-mm cross-sections using a standard No. 22 surgical blade. The resulting sections were aligned and embedded in 2% agar. After routine processing and paraffin embedment, 5–10 µm sections

were cut so that the resulting sections contained full cross-sections of the colon sampled along its entire length.

Laser capture microdissection

Deparaffinized 10 µm sections (xylene: one wash for 10 min and two subsequent washes of 5 min each; followed by 100% isopropanol: three washes of 5 min each) were air dried for 1 h in a desiccator. Parallel hematoxylin/eosin-stained sections were used as a guide for microdissection. Using a PixCell Ite LCM apparatus (LCM; Molecular Devices, Sunnyvale, CA, USA), two populations of microbes were sampled in the ascending colon: those in the spaces between the transverse folds (interfold) and those in the central lumen (digesta). Separate CapSure HS caps (Arcturus Engineering, Mountain View, CA, USA) were used for each region.

Microbial diversity by tag pyrosequencing analysis

Microbes from interfold and digesta regions were collected from intestinal sections ($n=3$ wild-type mice) by LCM. DNA was extracted from the LCM-sampled material using a QIAamp DNA Micro Kit (Qiagen, Valencia, CA, USA). Extracted DNA was used for tag-encoded pyrosequencing analysis of 16S rRNA genes using well-validated primers (27F and 338R), tags and protocols (Hamady *et al.*, 2008). PCR amplifications were performed in quadruplicate, and products were pooled. Purified PCR products were subjected to high-throughput pyrosequencing using the GS-FLX Titanium platform (Roche, Branford, CT, USA). Analysis of pyrosequencing reads was carried out using bioinformatics tools (Library Compare and Classifier) at the Ribosomal Database Project (RDP; release 10.15) (Wang *et al.*, 2007; Cole *et al.*, 2009). Differences in microbial composition were considered significant if $P<0.001$. A detailed description of this analysis is provided in Supplementary Methods. Pyrosequencing data is accessible in the European Nucleotide Archive (Short Read Archive) under accession number ERP000288.

Microbial density by qPCR assays

To determine microbial DNA concentrations from LCM-sampled material, we developed a qPCR assay based on amplification of the RNA polymerase beta subunit (*rpoB*), a gene highly conserved in Bacteria (Dahllof *et al.*, 2000; Case *et al.*, 2007; Adekambi *et al.*, 2008). An independent set of samples ($n=6$) was used to estimate densities of microbial populations. Intestinal sections were used to obtain material by LCM as described above. We used two independent sets of mice and two different DNA extraction methods as follows: (i) as described above and (ii) a modified and in-house validated DNA extraction method for paraffin wax-embedded

sections (Sepp *et al.*, 1994) (see detailed description in Supplementary Methods).

Extracted genomic DNA was used as a template for PCR amplification and quantification (ng of DNA/ μ l) of total Bacteria (*rpoB* gene) using SYBR Green PCR technology. The density of selected bacterial groups within interfold and digesta regions was determined by qPCR assays using previously validated group-specific primers. These qPCR assays targeted Bacteroidaceae–Porphyromonadaceae–Prevotellaceae, Lachnospiraceae–Ruminococcaceae, Enterococcaceae (Rinttila *et al.*, 2004) and Lactobacillaceae (Barman *et al.*, 2008). Primer set Lachnospiraceae–Ruminococcaceae targets 16S rRNA genes from members of Lachnospiraceae and Ruminococcaceae families (also known as *Clostridium* cluster XIVa or the *Eubacterium rectale*–*Clostridium coccoides* group). The theoretical 16S rRNA gene targets for this primer set are shown in Supplementary Table 1. See Supplementary Methods for a detailed description of the PCR protocols.

DNA concentrations (*rpoB* and 16S rRNA genes) in each LCM sample were determined using the absolute quantification method. Standard curves were constructed with fivefold dilutions of genomic DNA templates of known concentration. DNA extracted from mouse intestinal contents was used as a template for total Bacteria, whereas DNA extracted from laboratory-type strains was used for each of the selected bacterial groups. Concentrations of DNA used in the standard curves ranged from 20 ng to 1.3 pg μ l⁻¹. For each qPCR assay, standard curves were amplified at the same time as LCM samples. PCR amplifications were performed in triplicate. Bacterial group-specific qPCR signals were normalized (divided) to total Bacteria (*rpoB* gene) qPCR signal.

Fingerprinting analysis of Lachnospiraceae–Ruminococcaceae populations

Interindividual variations in diversity of 16S rRNA genes of families Lachnospiraceae–Ruminococcaceae were examined by PCR and terminal restriction fragment length polymorphism (Avaniss-Aghajani *et al.*, 1994). Genomic DNA obtained from LCM samples ($n=6$) was used as a template for PCR amplification using Lachnospiraceae–Ruminococcaceae-specific primers targeting 16S rRNA genes (Rinttila *et al.*, 2004) as described above, with the exception that the forward primer was 5'-end labeled with 6-carboxyfluorescein (6-FAM; Sigma-Aldrich, St Louis, MO, USA). Three independent restriction enzymes, *HpyCh4IV*, *HhaI* and *MseI*, were used for the digestion of Lachnospiraceae–Ruminococcaceae 16S rRNA gene amplicons. DNA fragment analysis was performed in duplicate on the ABI Prism 3730xl Analyzer (Applied Biosystems, Foster City, CA, USA) using GeneScan Liz600 marker (Applied Biosystems) as a size standard. Terminal-restriction-fragment profiles in each sample were obtained using GeneMapper software (version 3.7, Applied Biosystems).

See Supplementary Methods for a detailed description of the PCR-terminal restriction fragment length polymorphism protocol.

Profiles obtained from three independent restriction analyses were concatenated to form a collective data set, and the resulting output files were used in multivariate statistical analyses using non-metric multidimensional scaling analysis and the Kulczynski similarity index (presence-absence data) (Faith *et al.*, 1987; Noll *et al.*, 2008). Differences in microbial composition between the two regions were analyzed by non-parametric MANOVA. All multivariate statistical analyses were performed with the PAST software package (University of Oslo, Norway) (Hammer *et al.*, 2001; Rodriguez *et al.*, 2006; Scupham, 2009). Pairwise comparisons of α -diversity (profile similarity between different subjects) and β -diversity (profile similarity across the interfold and digesta regions) were examined by the Kulczynski similarity index and inferential statistics.

Identification of specific Lachnospiraceae and Ruminococcaceae species was carried out in the interfold region by random cloning and Sanger sequencing

Interfold and digesta regions were sampled by LCM from an independent set of wild-type mice ($n=3$). DNA was extracted from the LCM-sampled material using the method for paraffin wax-embedded sections as described above. PCR amplification of near full-length 16S rRNA genes was performed as described elsewhere (Eckburg *et al.*, 2005). See Supplementary Methods for a detailed description of the PCR and Sanger sequencing protocol. Chimera-free sequences were analyzed using the Classifier tool at RDP (Wang *et al.*, 2007). Sequences classified into the Clostridiales order (Lachnospiraceae and Ruminococcaceae families, and unclassified Clostridiales) were retrieved from the clone library and used for phylogenetic analysis to obtain an accurate taxonomic classification. In brief, the Seqmatch search at RDP (Wang *et al.*, 2007) was used to find and retrieve the closest matches for known-type strains. Phylogenetic analysis was performed using the maximum likelihood method (Eck and Dayhoff, 1966). See Supplementary Methods for detailed descriptions of phylogenetic analysis and statistical significance of branch order. The sequences of 16S rRNA genes identified in this work are deposited in GenBank under accession numbers: HM856189 through HM856324.

Statistical analysis

Comparisons of bacterial densities between interfold and digesta regions were performed by the Mann–Whitney–Wilcoxon test using SAS software (Statview, Version 5.0.1; SAS Institute, Cary, NC, USA). Pairwise comparisons of α -diversity and β -diversity were examined by the Kulczynski similarity index (presence-absence data) and

ANOVA-Fisher's Protected Least Significant Difference test using StatView version 5.0.1. Differences were considered significant at $P < 0.05$.

Results and discussion

Interfold and digesta regions of the mouse ascending colon contain distinct microbial populations

The mouse ascending colon contains transverse folds that project ≈ 1 mm into the lumen and are oriented in a direction perpendicular to the fecal stream (Figure 1a) (Hummel *et al.*, 1966). This portion of the mouse colon is of additional interest as similar structural folds are also found in the human intestine (plica lunaris and plica semilunaris in the small intestine and colon, respectively). Low-power views of this region in mouse showed that the lumen contained two distinct patterns: (i) dense material between the transverse folds (interfold region) and (ii) less dense, less homogeneous material including food particles within the central lumen (digesta region) (Figure 1b). Higher-power views of these sections showed that the material within the interfold region was comprised of compact, interlacing layers of large, slightly curved fusiform-shaped bacteria (> 5 – $10 \mu\text{m}$) (Figures 1c and d and Supplementary Figure 2A and B). In contrast, higher-power views of the central lumen

showed undigested food particles that were associated with 1– $2 \mu\text{m}$ rod- and coccoid-shaped bacteria (Figures 1e and f). Microbes with similar morphology have previously been described in these regions. (Davis *et al.*, 1973; Tannock 1987; Swidsinski *et al.*, 2007a,c). Our goal was to best characterize the interfold microbes using a high-resolution sampling method and current nucleic acid-based analytical techniques.

Use of LCM as a tool to characterize intact intestinal microbial populations

The sampling of region-specific microbes without a major disturbance to the luminal organization is a major challenge. Earlier studies used washes of the mucosal surface and biopsies to investigate microbes located near the mucosal surface (Eckburg *et al.*, 2005; Franke *et al.*, 2008; Hill *et al.*, 2009). To capture microbes from both the interfold and digesta regions, we used LCM. We, along with others, have used LCM for analysis of host-gene expression (Wong *et al.*, 2000; Stappenbeck *et al.*, 2002) and to isolate microbial DNA from specified host cells (Boye *et al.*, 2006; De Hertogh *et al.*, 2006; Molbak *et al.*, 2006). Although the interfold region measures on the order of $100 \mu\text{m}$ in greatest dimension, the high resolution of LCM ($\sim 5 \mu\text{m}$) permits easy and precise sample collection.

Figure 1 A morphologically distinct population of predominately fusiform-shaped bacteria is located between the transverse folds of the mouse ascending colon. (a) Hematoxylin/eosin and (b–f) periodic acid-schiff-stained sections of the mouse colon. (a) The proximal portion of the colon (ascending colon) contains transverse folds that project into the lumen (denoted by arrow). The digesta is food particle-associated material in the central lumen (denoted as dashed arrow). (b) Methacarn-fixed section of a mouse ascending colon. The transverse fold (outlined in black arrows) emanates from the mucosa, and is lined by an epithelium that contains periodic acid-schiff-positive goblet cells (denoted as blue arrowhead). Interfold and digesta regions collected by LCM are denoted by blue and black dashed lines, respectively. (c, d) Higher-power views of interfold region. Interlacing fusiform-shaped microbes (denoted as yellow arrowheads) are abundant in this region. (e, f) Higher-power views of the digesta shows rod- and coccoid-shaped microbes (denoted as blue boxes). Bars = 5 mm (a), 500 μm (b), 20 μm (c, e), 5 μm (d, f).

One of our initial concerns with isolation of bacterial DNA from methacarn-fixed material was that the number of Gram-positive bacteria can be underestimated within a complex sample because of the difficulties a Gram-positive cell wall poses to DNA extraction (Park, 2007). Therefore, we performed a preliminary mixing experiment using a Gram-positive (*Enterococcus faecalis*) and a Gram-negative type strain (*E. coli*). We placed defined ratios of these bacterial strains on slides. We then air dried, methacarn fixed and dehydrated the slides (in washes of ethanol and xylene). We then captured the bacteria and extracted their DNA. We found that we could efficiently detect both Gram-positive and Gram-negative type strains over a large linear range using qPCR assays targeting group-specific 16S rRNA genes (Supplementary Figure 3). An identical fixation and dehydration procedure was used for tissues prepared for LCM.

The interfold microbes are enriched for Lachnospiraceae and Ruminococcaceae families

To broadly screen LCM-sampled microbes from the interfold and digesta regions, we first used pyrosequencing, the current standard method to perform deep profiling of 16S rRNA genes in complex

microbial samples (Hamady *et al.*, 2008). Genomic DNA extracted from interfold and digesta samples was used for PCR amplification of 16S rRNA genes and for tag-encoded pyrosequencing analysis. A total of 42 635 and 53 748 reads were obtained from the interfold and digesta regions, respectively. After removing low-quality reads and sequences of <310 bases, we classified the remaining 29 560 sequences from the interfold region and 38 120 from the digesta region using the Library Compare tool at the RDP. The shapes of the rarefaction curves (Supplementary Figure 4) indicated that bacterial richness in the interfold and digesta regions was sufficient to ensure high coverage for both phyla and families (80% and 90% confidence intervals, respectively).

For both data sets, >96% of sequences were classified into six bacterial phyla. However, the majority of the sequences belonged to phyla Firmicutes and Bacteroidetes (94.4% versus 95.9% for interfold and digesta regions, respectively). These findings at the level of phyla are similar to those of other investigators using cecal contents, mucosal biopsies and fecal samples (Eckburg *et al.*, 2005; Ley *et al.*, 2005; Franke *et al.*, 2008; Garner *et al.*, 2009; Hill *et al.*, 2009; Salzman *et al.*, 2009). Interestingly, the interfold and digesta regions contained marked differences. Bacteroidetes were significantly

Figure 2 Colonic interfold microbes are enriched in Lachnospiraceae and Ruminococcaceae families. Pyrosequencing analysis was used to examine microbial diversity between interfold and digesta regions. (a) Comparisons of diversity at the phylum level. (b) Comparisons of diversity at the family level. Each chart represents the taxonomic composition. Sequences were obtained from pooled samples ($n = 3$) of interfolds (29560 reads) and the digesta (38120 reads) region. Lachnospiraceae and Ruminococcaceae are outlined with a dotted line to highlight these families. Unclassified Bacteroidetes and Firmicutes correspond to sequences not classifiable at family level (as of March 2010). Library Compare tool at RDP estimates the probability of observing a difference in a given taxon. Differences in taxa between interfold and digesta were considered significant if $P < 0.001$. * $P < 7E-03$, ** $P < 2E-11$ and *** $P = 6E-014$.

enriched in the digesta region (40% versus 16% of reads in the interfold region), whereas Firmicutes were significantly represented in the interfold region (78% versus 56% in the digesta; Figure 2a). The classification of digesta microbes into predominantly Firmicutes and Bacteroidetes concurs with previous studies of total luminal contents from the ileum, cecum and colon (Ley *et al.*, 2005; Garner *et al.*, 2009; Hill *et al.*, 2009; Salzman *et al.*, 2009).

A more limited number of studies have profiled mucosa-associated microbes from samples obtained by endoscopic biopsy or dissected/washed intestines (human and mouse samples, respectively). These studies found a trend for the enrichment of Firmicutes as compared with Bacteroidetes (Eckburg *et al.*, 2005; Frank *et al.*, 2007; Hill *et al.*, 2009). In our study, we found a more profound enrichment of Firmicutes.

Because of the significant enrichment of Firmicutes in the interfold region, we next examined differences at lower taxonomic levels. On the basis of the pyrosequencing analysis, the estimated microbial richness ranged between 645 and 934 Operational Taxonomic Units (OTUs) in the interfold region, and between 514 and 738 OTUs in the digesta region (95% and 97% confidence intervals, respectively). Moreover, Good's coverage, which accounts for both diversity and abundance of OTUs, revealed that 96.8% of the population (using a 97% confidence interval) was covered in the interfold region, whereas 98.0% was covered in the digesta region. These results indicated that the sequencing was of adequate depth for additional analysis. At the bacterial family level, 43% of the interfold region and 67% of the digesta region sequences were classified into 25 and 22 known families, respectively. With this subset of sequences from both regions, >98% were classified within seven bacterial families (Bacteroidaceae, Lachnospiraceae, Lactobacillaceae, Porphyromonadaceae, Prevotellaceae, Rikenellaceae and Ruminococcaceae; Figure 2b).

These differences at the level of phyla between the interfold and digesta regions were supported by specific differences in the representation of bacterial families. Strikingly, 20% of the sequences from the interfold region were classified in the *Clostridium* cluster XIVa group (Lachnospiraceae and Ruminococcaceae) (Collins *et al.*, 1994; Rainey and Janssen, 1995), compared with only 3% in the digesta region. Interestingly, these two bacterial families are known to be fusiform-shaped bacteria (Cotta and Forster, 2006), which correlates with the morphological findings in the interfold region (Figure 1). Thus, on the basis of these observations, we hypothesize that these fusiform-shaped microbes inhabiting the interfold region may represent members of the Lachnospiraceae and Ruminococcaceae families. Additional studies are needed to identify and functionally characterize these microbial communities.

Similar trends of enrichment for Lachnospiraceae and Ruminococcaceae sequences in samples taken

near the colonic mucosa were observed in three previous comprehensive studies of 16S rRNA gene repertoires (Eckburg *et al.*, 2005; Franke *et al.*, 2008; Hill *et al.*, 2009). However, their enrichment was not as robust as our findings. In mice, comparisons of 16S rRNA genes between total luminal contents and washed proximal and distal colons showed <2-fold enrichment in Lachnospiraceae and Ruminococcaceae at the mucosal surface (Hill *et al.*, 2009). In humans, sequences from these two bacterial families were enriched <2-fold in biopsy tissues compared with stool samples (Eckburg *et al.*, 2005). Therefore, the use of LCM to more precisely obtain microbial samples, and the use of local reference populations (interfold versus digesta regions), may facilitate the identification of mucosa-associated microbes in a model organism.

We then validated these findings using an independent set of wild-type mice and two independent analytical techniques to confirm that the Lachnospiraceae–Ruminococcaceae families were enriched in the interfold region. As above, we used LCM to sample microbes from the interfold and digesta regions. We first used isolated bacterial DNA to perform qPCR assays of the 16S rRNA gene. We used independent sets of LCM material from interfold and digesta regions ($n=6$ mice) as templates for qPCR using group-specific primers. These qPCR assays targeted Bacteroidaceae–Porphyromonadaceae–Prevotellaceae, Enterococcaceae, Lachnospiraceae–Ruminococcaceae and Lactobacillaceae 16S rRNA genes. For all groups, the limit of detection was ≤ 100 fg of DNA (Supplementary Figure 3).

Bacterial group-specific densities were normalized within each sample using the qPCR signal of the *rpoB* gene, a highly conserved gene in Bacteria that encodes for the β -subunit of RNA polymerase (Dahllof *et al.*, 2000; Case *et al.*, 2007; Adekambi *et al.*, 2008). These analyses showed that densities of Bacteroidaceae–Porphyromonadaceae–Prevotellaceae ($P=0.0374$), Enterococcaceae ($P=0.0065$) and Lactobacillaceae ($P=0.0104$) were significantly greater in the digesta region, compared with the interfold region. In contrast, the density of Lachnospiraceae–Ruminococcaceae was significantly enriched ($P=0.0374$) in the interfold region compared with the digesta region (Figures 3a–d). These results confirmed that the composition of microbial communities differs significantly between the interfold and digesta regions, and that Lachnospiraceae and Ruminococcaceae are predominant families inhabiting the interfold region.

We next determined the microbial composition in the interfold and digesta regions (the same samples as were used for qPCR analysis above) using a combination of bacterial group-specific PCR and terminal restriction fragment length polymorphism techniques. Multivariate non-metric multidimensional scaling analysis ordinations derived from the Kulczynski similarity index (presence-absence data) and MANOVA statistics confirmed that the

Figure 3 Colonic interfolds harbor higher density of microbes of the families Lachnospiraceae–Ruminococcaceae. (a–d) Bacterial densities of interfold and digesta regions were examined using bacterial group-specific qPCR assays. The data depict density of each bacterial group relative to total Bacteria (*rpoB* gene) as measured by qPCR and DNA standard curves. Bacterial group-specific qPCR signals were normalized (divided) to total Bacteria (*rpoB* gene) qPCR signal. The *rpoB* is a gene highly conserved in the Bacteria domain. The asterisk in **a** indicates that the group queried by this primer set also amplifies 16S rRNA genes of Bacteroidaceae, Porphyromonadaceae and Prevotellaceae. Each PCR assay was performed in triplicate. Bars in each figure represent mean values + s.e. ($n = 6$). Comparisons were made using the Mann–Whitney–Wilcoxon test. Differences were considered significant if $P < 0.05$. Results of qPCR assays are shown in box plots and include their five-number summaries (the smallest observation, lower quartile, median, upper quartile and largest observation).

Figure 4 Lachnospiraceae–Ruminococcaceae populations are distinct in the interfold region compared with the digesta region. Interindividual variation of Lachnospiraceae–Ruminococcaceae was examined by PCR and terminal restriction fragment length polymorphism techniques targeting Lachnospiraceae–Ruminococcaceae-specific 16S rRNA genes. (a) Differences in the structure and composition of this bacterial family between the interfold (black symbols) and digesta (gray symbols) regions were examined by multivariate analysis ($n = 6$). Non-metric multidimensional scaling analysis ordinations derived from the Kulczynski similarity index (presence-absence data). Each symbol is representative of a single sample. Samples are plotted along the first two component axes. The ellipse corresponds to the joint 95% confidence limits. Microbial composition between the two regions was compared using non-parametric MANOVA. (b) Pairwise comparisons of α -diversity (profile similarity between different subjects, that is, interfold versus interfold) and β -diversity (profile similarity across the interfold and digesta regions) were examined by the Kulczynski similarity index (presence-absence data) and inferential statistics. ANOVA and Protected Least-Significant Difference test were used to compare differences in α -diversity and β -diversity. Differences were considered significant at $P < 0.05$.

composition of Lachnospiraceae–Ruminococcaceae 16S rRNA genes from the interfold region is distinct from that observed in the digesta region (Figure 4a).

Using the same 16S rRNA gene profiles, we analyzed α -diversity and β -diversity to evaluate interindividual differences in the Lachnospiraceae–Ruminococcaceae composition of the interfold and digesta regions.

Pairwise comparisons of the Kulczynski similarity index showed that α -diversity of these two bacterial populations between different replicate animals was more homogenous than β -diversity across the interfold and digesta regions (Figure 4b). These results further support the idea that the interfold region is inhabited by a different Lachnospiraceae–Ruminococcaceae

community when compared with the digesta region, and that the structure of this bacterial family is similar in replicate animals.

Identification of specific Lachnospiraceae and Ruminococcaceae species in the interfold region by random cloning and Sanger sequencing

To more precisely classify Lachnospiraceae and Ruminococcaceae bacterial species (OTUs) in the interfold region, we performed Sanger sequencing using an independent set of wild-type mice ($n=3$). Genomic DNA sampled by LCM was used for the amplification of near full-length 'universal' 16S rRNA genes. These PCR products (≈ 1.5 kb) were cloned, sequenced and aligned to sequences archived in the Greengenes 16S rRNA database. A total of 873 chimera-free clones, interfold (496 clones) and digesta

regions (377 clones), were compared using the Library Compare tool at RDP. From the interfold region, 136 sequences were classified into the Clostridiales order (Lachnospiraceae and Ruminococcaceae families, and unclassified Clostridiales), whereas only five sequences were similarly classified from the digesta region. The interfold sequences were retrieved from the clone library for more accurate classification using phylogenetic analyses. First, the closest matches for known-type strains were obtained using the Seqmatch search at RDP. This analysis revealed that at least 106 OTUs were enriched in the interfold region. These OTUs were classified into 17 candidate genera ($\approx 95\%$ confidence interval) in the family Lachnospiraceae, into 7 genera in the Family Ruminococcaceae and into 10 genera of the *Clostridium* cluster XIV (Collins et al., 1994) (Table 1). Topology of maximum likelihood trees confirmed that these OTUs were

Table 1 Operational taxonomical units of families Lachnospiraceae, Ruminococcaceae unclassified Clostridiales (*Clostridium* cluster XIV) enriched in the interfold region

Family	Number of 16S rRNA gene sequences	Similarity range	Best match (type strain) ^a
Lachnospiraceae	17	0.91–0.83	<i>Robinsoniella peoriensis</i> ; PPC31; AF445285

Similarity score reported by SeqMatch at the RDP.

^aClosest matches for known type strains were obtained using the Seqmatch search at RDP (see *Material and methods*). Species, strain ID and accession number are provided.

Figure 5 Candidate genera of families Lachnospiraceae, Ruminococcaceae and *Clostridium* cluster XIV in the interfold region. To obtain a more precise classification of Lachnospiraceae and Ruminococcaceae bacterial species (Operational Taxonomic Units; OTUs) in the interfold region, Sanger sequencing was performed and reads were analyzed using the Seqmatch search at RDP and phylogenetic analysis. At least 106 OTUs of families Lachnospiraceae, Ruminococcaceae and *Clostridium* cluster XIV were present in the interfold region (denoted by a red circle). The closest matches for known-type strains were identified and retrieved from RDP using Seqmatch search (see Table 1 for accession numbers, number of sequences in each group and similarity values). Topology of maximum likelihood trees confirmed that these OTUs were related to members of families Lachnospiraceae, Ruminococcaceae and the *Clostridium* cluster XIV. This tree was rooted using *Aquifex pyrophilus*, the closest genus to the bacterial last common ancestor. Branches of major clades are depicted by different colors. Branches of unclassified Clostridiales were collapsed (red leaf, 51 sequences). The statistical significance of branch order was estimated by the generation of 1000 replications of bootstrap resampling of the originally aligned nucleotide sequences. Scale represents nucleotide substitutions per site.

closely related to members of families Lachnospiraceae and Ruminococcaceae, as well as to the *Clostridium* cluster XIV (Figure 5). These two

analyses, SeqMatch search and maximum likelihood phylogeny, revealed that most of the microbes inhabiting the interfold region represent novel OTUs

(83–96% confidence interval range), and many of these microbes have not yet been cultured. Taken together, these analyses revealed that the microbes enriched in the interfold region comprise a population of largely uncharacterized microbes. Therefore, cultivation of representative microbes located in this region should be a priority.

Collectively, these results emphasize the need for novel experimental systems (animal models and bacterial strains) to discern basic biological principles regulating the interactions between mucosa-associated microbes and the host immune system. Interestingly, clinical evidence has linked a reduced intestinal colonization by members of Lachnospiraceae and Ruminococcaceae families to chronic intestinal disorders, such as inflammatory bowel disease (Sokol *et al.*, 2008, 2009; Willing *et al.*, 2009).

In summary, this study has established new insights into the spatial organization and diversity of microbes across the murine intestinal lumen. Using a high-resolution microbial capture system in conjunction with current nucleic acid analytic techniques, we showed that the microbial communities of the interfold and digesta regions were remarkably different. The significance of this finding is that the enriched families in the interfold region may be positioned to perform critical physiological/barrier functions as consortium. To understand the ecology of this consortium will be a challenge and many members of this community have not yet been cultured. We hope that this study will provide a roadmap to design strategies for culture-based studies. Finally, we propose that the studies in this model organism will provide a strategy to identify and study similar bacterial families that reside in the human intestine.
