An unusual symbiosis, first observed at ~3000 m depth in the Monterey Submarine Canyon, involves gutless marine polychaetes of the genus *Osedax* and intracellular endosymbionts belonging to the order Oceanospirillales. Ecologically, these worms and their microbial symbionts have a substantial role in the cycling of carbon from deep-sea whale fall carcasses. Microheterogeneity exists among the *Osedax* symbionts examined so far, and in the present study the genomes of the two dominant symbionts, Rs1 and Rs2, were sequenced. The genomes revealed heterotrophic versatility in carbon, phosphate and iron uptake, strategies for intracellular survival, evidence for an independent existence, and numerous potential virulence capabilities. The presence of specific permeases and peptidases (of glycine, proline and hydroxyproline), and numerous peptide transporters, suggests the use of degraded proteins, likely originating from collagenous bone matter, by the *Osedax* symbionts. ¹³C tracer experiments confirmed the assimilation of glycine/proline, as well as monosaccharides, by *Osedax*. The Rs1 and Rs2 symbionts are genomically distinct in carbon and sulfur metabolism, respiration, and cell wall composition, among others. Differences between Rs1 and Rs2 and phylogenetic analysis of chemotaxis-related genes within individuals of symbiont Rs1 revealed the influence of the relative age of the whale fall environment and support possible local niche adaptation of ‘free-living’ lifestyles. Future genomic examinations of other horizontally-propagated intracellular symbionts will likely enhance our understanding of the contribution of intraspecific symbiont diversity to the ecological diversification of the intact association, as well as the maintenance of host diversity.

Subject Category: Microbe-microbe and microbe-host interactions

Keywords: *Osedax*; symbionts; deep sea; Oceanospirillales; whale fall

Introduction

Nutritional symbioses involving bacteria and their invertebrate hosts have critical roles in sustaining high productivity in many marine environments. Some of these invertebrate taxa transmit their essential symbionts vertically through eggs, but surprisingly, many acquire their symbionts horizontally from the environment (Bright and Bulgheresi, 2010). Environmental symbionts must therefore face conflicting selective pressures for their host-

associated and free-living subpopulations. Coevolutionary pressures will constrain changes to bacterial genes that facilitate infection of aposymbiotic invertebrate larvae, engage in ‘hand-shaking’ with the host genome to avoid exclusion and coordinate metabolic interdependencies, as well as genes that enhance metabolism and reproduction in the host cytosol. The free-living subpopulation, on the other hand, might favor genes that slow metabolism and reproduction and enhance survival under nutrient-limited conditions (for example, in the deep sea). New details have emerged regarding the range of adaptations used by endosymbionts, parallels with pathogens, provisioning from symbiont to host and many ecological aspects, including transmission between host generations and the duality of negotiating between host-associated and free-living lifestyles. Recent advances in molecular biology and genomics have enabled this insight for

chemosynthetic symbionts, in particular, hosted by the marine oligochaete *Olavius algarvensis* (Woyke *et al.*, 2006), vesicomyid clam species (Kuwahara *et al.*, 2007; Newton *et al.*, 2007), the siboglinid tubeworm *Riftia pachyptila* (Robidart *et al.*, 2008) and the heterotrophic symbionts of wood-boring bivalves (Yang *et al.*, 2009).

An unusual symbiosis involving gutless marine polychaetes of the genus *Osedax* and heterotrophic gammaproteobacteria belonging to the order Oceanospirillales was first observed in 2002 living on a gray whale skeleton at ~3000 m depth in the Monterey Submarine Canyon, California (Goffredi *et al.*, 2004; Rouse *et al.*, 2004). Now, 17 morphologically diverse species are known worldwide from depths ranging from 25 to 3000 meters (Goffredi *et al.*, 2004; Rouse *et al.*, 2004; Glover *et al.*, 2005; Fujikura *et al.*, 2006; Braby *et al.*, 2007; Vrijenhoek *et al.*, 2009; Salathé and Vrijenhoek, 2012). Evidence for *Osedax* borings in fossilized bones suggests that the genus has historically colonized a large portion of the world's oceans (Higgs *et al.*, 2011; Kiel *et al.*, 2011; Higgs *et al.*, 2012). Much is now known about the role of these worms in degrading sunken bones and the recycling of deep-sea carbon (Goffredi *et al.*, 2005; Braby *et al.*, 2007), their phylogenetic relationships (Vrijenhoek *et al.*, 2009; Hilário *et al.*, 2011), and an unusual reproductive strategy that involves dwarf males and environmental sex determination (Rouse *et al.*, 2008; Vrijenhoek *et al.*, 2008; Rouse *et al.*, 2011; Miyamoto *et al.*, 2013).

Osedax are unique among members of the polychaete family Siboglinidae in that they possess a complex system of 'roots' with an ovisac covered by tissue which houses intracellular bacteria (Table 5; Goffredi *et al.*, 2004). Collagen from bone appears to be their nutritional foundation, based on $\delta^{13}\text{C}$ signatures that are consistent between *Osedax* tissues and the collagen-specific fraction in whale bones (Goffredi *et al.*, 2005). The worms are hypothesized to use acidifying vacuolar H^+ -ATPases in their root-like tissue to bore into and breakdown the hard, calcified matrix of bones (Tresguerres *et al.*, 2013). Based on unsuccessful attempts at PCR amplification of genes required for autotrophic CO_2 fixation (that is, ribulose-1, 5-bisphosphate carboxylase/oxygenase and ATP citrate lyase), the symbionts are hypothesized to be uniquely heterotrophic, rather than chemosynthetic, as in all other examined siboglinids (Goffredi *et al.*, 2005). The symbionts are likely responsible for at least some of the nutritional needs of the host, as evidenced by concordant $\delta^{13}\text{C}$ compound-specific isotopic measures between symbiont-derived fatty acids and host-produced wax esters (Goffredi *et al.*, 2005, 2007). The specific nature of the symbiont metabolism, and any exchange of compounds, however, has yet to be elucidated.

All species of *Osedax* examined to date host related bacteria from the Oceanospirillales order of

Gammaproteobacteria (Goffredi *et al.*, 2005, 2007; Verna *et al.*, 2010; Salathé and Vrijenhoek, 2012). In this study, we examine the dominant symbiont 'ribospecies' Rs1 and Rs2 associated with *Osedax rubiplumus* and *Osedax frankpressi* living at 1820–2891 m depths in Monterey Canyon (Goffredi *et al.*, 2005; Salathé and Vrijenhoek, 2012). A previous study noted that the frequencies of Rs1 and Rs2 symbionts hosted by these worms varied as the bones decompose and that the observed temporal shifts are independent of host species, suggesting a direct influence of the local environment on symbiont populations (Salathé and Vrijenhoek, 2012). A genomic comparison of the two dominant symbiont types in *Osedax* worms offers the opportunity to elucidate details regarding their specific metabolism and to assess whether spatial or temporal heterogeneity, even within the deep sea, can influence biological diversity.

Materials and methods

Sample collection

Females of *Osedax frankpressi* were collected for genome analysis from a whale fall at 1891 m depth in Monterey Canyon (36.708 N/–122.105 W; dive DR236, on 5 June 2011; Table 5, Supplementary Table S1). Additional samples of two host species (*O. frankpressi* and *O. rubiplumus*) from two locations (1891 m and 2891 m depth; the latter of which is at 36.313 N/–122.434 W) were collected over the course of 112 months (between 2002 and 2011; Supplementary Table S1), for PCR-based analysis of both symbiont identity and functional gene characteristics, described below. Finally, *O. roseus* worms for experiments with ^{13}C -labeled substrate were collected from a whale fall at 840 m depth off southern California (32.767 N/–117.483 W; dive DR471, on 18 May 2013).

DNA extraction and evaluation of purity

For genomic analysis, host root tissues were loosely homogenized in ice-cold $1\times$ phosphate-buffered saline using a Kontes ground glass homogenizer. Symbionts were enriched via selective filtration from homogenate (3 μm pre-filter and final 0.22 μm filter), and collected on a hydrophilic Durapore membrane (Millipore, Billerica, MA, USA). Purity of captured cells was evaluated via fluorescence microscopy (DAPI and FISH, according to Goffredi *et al.* (2005)), before proceeding to nucleic acid extraction. DNA extraction directly from filters was performed using the Qiagen DNeasy kit (Valencia, CA, USA), following the manufacturer's protocol, with the exception of an initial overnight lysis in 400 μl of ATL buffer and proteinase K. Symbiont identity for each sample was determined via molecular analysis, described below, and two samples containing the Rs1 and Rs2 symbionts were

chosen for further genomic analysis. For simplification, we have maintained the ribospecies numbers (Rs1 and Rs2; Figure 1) associated with each symbiont based on the designation by Salathé and Vrijenhoek (2012), which correspond to the original 16S rRNA GenBank submissions AY549005 and AY549004, respectively (Goffredi *et al.*, 2005). The amount of extracted DNA, calculated using a Qubit fluorometer (Invitrogen) and Quant-iT PicoGreen (Invitrogen), was 150 and 50 ng for the Rs1 and Rs2 symbiont samples, respectively.

To ensure the relative symbiont purity in the nucleic acid extractions, we examined the microbial composition of the 16S ribosomal RNA gene (V1–V3 region) via pyrosequencing, according to Chun *et al.* (2010) (see Supplementary Methods for more details). Subsequent genomic analysis was performed on two samples that were determined to be relatively pure, one from each symbiont type, based on dominance of the target Oceanospirillales symbiont, which comprised 84% and 56% of the recovered 16S rRNA barcodes for symbionts Rs1 and Rs2, respectively (Supplementary Figure S1). The genomic DNA from both samples was subjected to whole-genome multiple displacement amplification (MDA) using the REPLI-g Mini kit (Qiagen) according to the manufacturer's recommendations. A UV irradiation method was employed to eliminate exogenous contaminant DNA found in MDA reagents (Woyke *et al.*, 2011) and 25 independent

amplification reactions were pooled for further analysis. Before genome sequencing, amplified DNA (~20 µg) was purified using the QIAamp DNA Mini kit (Qiagen) following the manufacturer's supplementary protocol.

Genome sequencing, assembly and partitioning

The *Osedax* symbiont Rs1 genome was sequenced using a combination of both Illumina and 454 FLX sequencing, from both a non-amplified and MDA-amplified nucleic acid extraction, described above. A 150-bp paired-end library was prepared from 8 ng of the non-amplified metagenomic DNA using the Nextera DNA sample preparation kit (Illumina, San Diego, CA, USA) and a total of 6 163 796 reads were obtained using an Illumina MiSeq instrument. Sequencing of the MDA-amplified Rs1 sample was performed from both an Illumina GAIIx 100 bp paired-end library (using the TruSeq DNA sample preparation kit) and from a 454 FLX Titanium 8-kb-span paired-end library (according to the Roche/454 protocol for titanium shotgun libraries), both from 5 µg of the MDA-amplified sample. A total of 203 574 paired reads were obtained from the 454 FLX run (average length = 356 bp), whereas 61 819 346 were obtained from the Illumina run. The *Osedax* symbiont Rs2 genome was sequenced from an Illumina GAIIx 100-bp paired-end shotgun library, prepared from 5 µg of the purified MDA

Figure 1 Phylogenetic relationships among the *Osedax* symbionts, based on the 16S rRNA gene. Additional sequences were obtained from GenBank and aligned using the ARB automated alignment tool with subsequent manual refinements. Taxa in bold denote those discussed in detail in this paper. The bacterial 16S rRNA-encoding sequences in the metagenomic sequencing reads for *Osedax* symbiont Rs1 were extracted using rRNASelector program. Fragments that showed overlap with an rRNA (> 60 bp; HMM profile with *E*-value lower than 10^{-5}) were identified as rRNA-coding regions. The 16S rRNA gene of the symbiont Rs2 sample was acquired via manual assembly of the 16S rRNA community sequence data, before metagenomic sequencing. For near full-length representatives and closest relatives, neighbor-joining analysis was conducted with Olsen distance correction. *Colwellia piezophila* (AB094412) was used as the outgroup. A more detailed phylogeny can be found in Salathé and Vrijenhoek (2012).

using the TruSeq DNA Sample Preparation kit (Illumina) and a total of 58 078 116 reads were obtained. The specific construction of shotgun libraries and Illumina/454 sequencing was performed at ChunLab, Inc. (Seoul, Korea).

Redundant high-coverage reads and sequencing errors from the MDA-amplified samples were removed via 'digital normalization' according to Brown *et al.* (2012). The resulting Illumina sequences for both genomes were assembled using CLC genomics wb5 (CLC Bio, Aarhus, Denmark), whereas the 454 reads of the Rs1 genome were assembled using the Newbler assembler 2.3 (Roche Diagnostics, Indianapolis, IN, USA). For the *Osedax* symbiont Rs1 genome, a hybrid assembly of both Illumina runs (non-amplified Nextera and MDA-amplified) and the 454 contigs was performed using CLC Genomics Workbench 5 and CodonCode Aligner (CodonCode Co, Centerville, MA, USA). The assembled contigs were subjected to *in silico* separation of the target genome from other possible metagenomic data sets using pentanucleotide content analysis as described previously (Woyke *et al.*, 2006; Kanehisa *et al.*, 2010; custom java code available at <http://sw.ezbiocloud.net>; Supplementary Figure S2 and Supplementary Results). In cases where a unique capability was attributed to the target symbiont genome, the partition to which it belonged was confirmed via recruitment and mapping of the contig against the bin, as well as the phylogenetic placement of surrounding contiguous genes.

Open-reading frames were predicted using Glimmer 3 (Delcher *et al.*, 2007) and the assembled contigs and scaffolds were uploaded into the RAST server (Aziz *et al.*, 2008). The predicted ORFs were annotated by searching against clusters of orthologous groups (COGs; Tatusov *et al.*, 1997) and SEED databases (Disz *et al.*, 2010). A comparative method was also employed, as described previously by Chun *et al.* (2009), in which target contigs with homology to a query ORF (>50% amino-acid sequence over 50% of the length of the gene) were identified using BLASTN. Nucleotide sequences of the query ORF, and selection of target homologous regions, were then aligned using a pairwise global alignment algorithm (Myers and Miller, 1988). Orthologs and paralogs were differentiated by reciprocal comparison. A comparison of ORFs present in both symbiont types, versus *Neptuniibacter caesariensis* and *Neptunomonas japonica*, was conducted using Venny (Figure 2; Oliveros, 2007).

Phylogenetic analysis—Average nucleotide identity of ORFs

A phylogenetic analysis, using highly conserved orthologous genes, compared the genomes of the *Osedax* symbionts Rs1 and Rs2 with 16 other *Oceanospirillales* genomes available in public databases. A set of 304 ORFs (107 966 amino acids) showing greater than 40% amino-acid sequence

Figure 2 Common and unique genes in the *Osedax* symbionts Rs1 and Rs2, in comparison with the closest relatives *Neptuniibacter caesariensis* and *Neptunomonas japonicus*, obtained by bidirectional best-hit analysis of all protein sequences in each genome. The Venn diagrams depict the overlap of those genes for which the function was assigned (that is, not hypothetical) and which were not duplicated. Unique genes may include some paralogs within each genome.

similarity to symbiont Rs1, over 70% of the length of the gene, was selected as highly conserved and aligned using CLUSTALX (Thompson *et al.*, 2002). Multiple alignments were concatenated and then used to construct a genome tree using the neighbor-joining method implemented in MEGA (Saitou and Nei, 1987; Kumar *et al.*, 2008). An evolutionary distance matrix for the neighbor-joining tree was generated according to the model of Jukes and Cantor (1969) and the resulting tree topology was evaluated by bootstrap analysis (Figure 3; Felsenstein, 1985). Evolutionary distance between the symbionts, and other relatives, was measured by the average nucleotide identity (ANI), computed by a BLAST algorithm, as previously described (Konstantinidis and Tiedje, 2005; Goris *et al.*, 2007).

Completeness estimation

Completeness of the genomes was estimated via the presence of 111 universal bacterial genes, identified by Dupont *et al.* (2012), using hmmer3 (Finn *et al.*, 2011), requiring 70% length match for each HMM, with the trusted cutoff as the minimum score (Supplementary Table S2). As many of the universal core genes are co-localized, including ribosomal and *sec* translocase genes, an additional estimate of completeness for symbiont Rs2 was assessed by comparison of ~169 lineage-specific uniformly spaced single-copy genes, identified in a minimum of 95% of gammaproteobacteria genomes in IMG release 4.0 (out of 418 genomes). The scripts for both estimates are available at <https://github.com/Ecogenomics/CheckM>.

Diagnostic symbiont and host identification

Samples were extracted using the Qiagen DNeasy kit, according to manufacturer's instructions. Symbiont

Figure 3 Genomic relatedness of the *Osedax* symbionts to 17 other bacteria within the order Oceanospirillales available in public databases (an ‘*’ denotes genomes from this study). The comparison is based on sequence similarity among a set of 300 highly conserved orthologous genes, showing greater than 40% amino-acid sequence similarity to *Osedax* symbiont Rs1. Sequences were aligned using CLUSTALX and multiple alignments were concatenated and then used to construct a genome tree using the neighbor-joining method implemented in MEGA. An evolutionary distance matrix for the neighbor-joining tree was generated according to the model of Jukes and Cantor (1969) and the resulting tree topology was evaluated by bootstrap analysis (numbers at nodes indicate bootstrap support from 1000 re-sampled data sets). The scale bar represents 0.05 substitutions per site.

and host identities of these individual worms were confirmed by amplification and sequencing of the symbiont 16S rRNA and host 18S rRNA (or cytochrome *c* oxidase) genes. A low-cost alternative for determining the dominant symbiont strain within each worm involved the specific amplification of the symbiont 16S rRNA gene, using an Oceanospirillales-specific primer pair (Supplementary Table S3; Rouse *et al.*, 2011), followed by subsequent digestion with *EcoRI*, *HaeIII* and *AluI* (New England Biolabs, Ipswich, MA, USA), according to the manufacturer’s recommendation. The specific pattern indicative of each symbiont (Supplementary Figure S3) was confirmed via direct sequencing (Laragen, Culver City, CA, USA), according to Goffredi *et al.*, 2012. Sequences were assembled and edited using Sequencher v4.10.1 (GeneCodes Corp., Ann Arbor, MI, USA) and compiled in ARB, after initial alignment using the SILVA Aligner function (Ludwig *et al.*, 2004; Pruesse *et al.*, 2007). Additionally, bacterial 16S rRNA-encoding sequences in the subsequent metagenomic sequencing reads for *Osedax* symbiont Rs1 were extracted using rRNASelector program (Lee *et al.*, 2011). Fragments that showed overlap with an rRNA (>60 bp; HMM profile with E-value lower than 10^{-5}) were identified as rRNA-coding regions and extracted (Figure 1; GenBank acc. no. KC862278). The 16S rRNA gene of the symbiont Rs2 sample was acquired via manual assembly of the 16S rRNA community sequence data, before metagenomic sequencing (Figure 1, acc. no.

KC862279). Host identities were confirmed via amplification and sequencing of either COI or 18S rRNA gene sequences (see Supplementary Table S3) compared, via BLASTN, to *Osedax* host sequences available in GenBank.

The *soxB* gene (sulfate thioesterase/sulfate thiohydrolase) was amplified using previously published primers 432F/1446R (or 693F/1446R) and PCR conditions (Supplementary Table S3, Supplementary Figure S4), and sequenced using an Applied BioSystems (Foster City, CA, USA) 3500xL Genetic Analyzer. Additionally, a targeted gene amplification approach from worms specifically infected by symbiont Rs1 (both *O. rubiplumus* and *O. frankpressi*, was performed for two methyl-accepting chemotaxis genes (*mcp3*, *mcp4*), the histidine protein kinase *cheA* gene, the methyltransferase *cheR* gene, and the methyl-esterase gene *cheB*, using primers designed in this study and conditions shown in Supplementary Table S3. Sequences were assembled, edited and translated using Sequencher v4.10.1 (GeneCodes Corp.) and a concatenation, in the case of *mcp* and *che* genes, was compared via neighbor-joining analysis (Figure 4).

Nucleotide sequence accession numbers

The *Osedax* symbiont genomes were deposited in GenBank under accession number PRJNA191058 (symbiont Rs1) and PRJNA191057 (symbiont Rs2).

Figure 4 Phylogenetic relationships among chemotaxis-related functional genes, based on amino-acid divergence, for *Osedax* symbiont Rs1 individuals with identical 16S rRNA genes, collected from two different species (*Osedax rubiplumus* (Or) and *O. frankpressi* (Ofp)), from two different sites, over 112 months. The midpoint-rooted neighbor-joining distance tree shown here was constructed from an alignment of five concatenated genes, including two methyl-accepting chemotaxis genes (*mcp3*, *mcp4*), the histidine protein kinase *cheA* gene, the methyltransferase *cheR* gene, and the methylesterase gene *cheB*. Two main clades cluster by early and late periods of time on the seafloor, with the early group showing a possible relationship to host species. Dive numbers begin with the remotely operated vehicle name; T = *Tiburion*, DR = *Doc Ricketts* (both owned and operated by the Monterey Bay Aquarium Research Institute). The number in parentheses indicates the number of worms analyzed from each dive. Genes amplified from the *Osedax* symbiont Rs1 corresponding to the genome sample was collected during dive DR236 (1*).

GenBank accession numbers for *cheA*, *cheB*, *cheR* and *mcp2* gene sequences obtained in this study are KC814720–KC814787. The GenBank accession number for the *soxB* gene from symbiont Rs2 is KF444201. Sequences that were shorter than 200 bp length, yet still informative with regard to ecotype distinctions between symbiont populations, including *mcp3* and *mcp4*, can be found in Supplementary Figure S5. GenBank accession numbers for the 16S rRNA sequences corresponding to symbionts in this study are KC862278 (Rs1) and KC862279 (Rs2).

Carbon elemental analysis

On collection, worms for ^{13}C tracer experiments were carefully removed from substrate and incubated, for 65 h at 4 °C on board ship in glass vials, in the presence of various substrates, of which ~20% was ^{13}C -labeled (in 100 ml 0.2 μm -filtered sea water; Table 5). Before analysis, specimens were divided into root and trunk tissues (symbiont- and non-symbiont containing, respectively) and were washed with 1 $\times$ phosphate-buffered solution (PBS) to remove residual-labeled salts. The uptake of ^{13}C label was then analyzed via elemental analysis isotope ratio mass spectrometry. Inorganic carbon was dissolved by acidification with 85% phosphoric for 2 h at 50 °C. Samples (0.2–1.2 mg) were lyophilized and transferred to tin capsules (9 $\times$ 5 mm). $\delta^{13}\text{C}$ of bulk organic matter and weight percent total organic carbon were determined via continuous flow

(He; 100 ml min $^{-1}$) on a Costech Instruments Elemental Combustion System model 4010 (EA) by oxidation at 980 °C over chromium (III) oxide and silvered cobalt (II, III) oxide followed by reduction over elemental copper at 650 °C. CO_2 was subsequently passed through a water trap and a 5-Å molecular sieve GC at 50 °C to separate N_2 from CO_2 . CO_2 was diluted with helium in a Conflo IV interface/open split before analysis. $\delta^{13}\text{C}$ values were measured on a Thermo Scientific Delta V Plus irMS. $\delta^{13}\text{C}$ and values were corrected for sample size dependency and then normalized to the VPDB scale with a two-point calibration and internal standards (Coplen *et al.*, 2006). Accuracy was $\pm 0.09\%$ ($n = 20$) and precision was $\pm 0.02\%$ ($n = 5$; 1σ), determined by analyzing independent standards as samples and precision was determined from international standards.

Results and discussion

Here, we describe the genomes of the two dominant Oceanospirillales symbionts found in association with the deep-sea polychaete genus *Osedax*. Evidence from comparative analysis among free-living relatives and a related symbiont of marine bivalves, suggests metabolic versatility, strategies for intracellular survival, potential virulence capabilities and evidence for local niche adaptation between ribospecies of the free-living lifestyles of the *Osedax* symbionts (Rs1 and Rs2).

General genomic features.

The *Osedax* symbiont Rs1 hybrid genome assembly resulted in 231 contigs (average length of 19.4 kb, range 1–180 kb), and 47 scaffolds ranging from 2 to 480 kb, with a total approximate length of 4 512 748 bp (Table 1; Figure 5). This genome was estimated to be ~94% complete with the singular occurrence of 104/111 core genes (Supplementary Table S2). For the *Osedax* symbiont Rs2 genome assembly, 411 contigs were acquired (average length of 12.8 kb, range 1–76 kb), with a total approximate length of 4 649 842 bp, and an estimate of 66% completeness (73/111 core genes; Table 1; Supplementary Table S2; Figure 5). As many of the genes that were missing from the symbiont Rs2 genome were ribosomal genes ($n = 22$; Supplementary Table S2), which are typically co-localized on the genome, a further assessment of 169 lineage-specific uniformly-spaced core genes shared among gamma-proteobacteria revealed the symbiont Rs2 genome to be ~89% complete. Despite an initial contamination of this sample by *Cytophaga*-related sequences, the occurrence of single-copy core genes after binning (that is, *dnaK*, *gyrA*, *pgk*, *rpoC*, *secA*; Supplementary Table S2), suggests that the symbiont Rs2 genome contains information from the symbiont only. Both symbiont genomes are within the range of previous estimates in close relatives for genome size (3.9–5.2 Mb), as well as the number of coding genes (3500–4700; Table 1). Coding density for each of the symbiont genomes was ~80% and, after binning, 84% of the annotations in both genomes were most similar to those within the gammaproteobacteria (Supplementary Figure S1).

Phylogenetic affiliation

A phylogenetic analysis, based on 304 highly conserved orthologous genes, was used to describe the genetic relatedness between the *Osedax* symbionts Rs1 and Rs2 to 17 other Oceanospirillales available in public databases (Figure 3). Based on

this lineage-specific analysis, the symbionts were most closely related to each other, and formed a monophyletic clade within the radiation of the order Oceanospirillales, consistent with single gene 16S rRNA analysis (Figure 3; Goffredi *et al.*, 2007; Salathé and Vrijenhoek, 2012). The symbionts shared an average genome nucleotide identity

Figure 5 Circular representation of the genome of *Osedax* symbiont Rs1, and comparison with symbiont Rs2, generated using Circos 0.52 (Krzywinski *et al.*, 2009). The outer rings 1 and 2 represent the coding regions of symbiont Rs1, which are color coded according to the COG functional classes as designated in the inset at left and defined in Supplementary Table S5. Ring 3 shows the position of rRNAs and tRNAs in symbiont Rs1. Ring 4 represents the genome of symbiont Rs2, color coded according to homology with the genes of symbiont Rs1, depicted in the inset at right. Rings 5 and 6 are G+C content and G+C skew, respectively. The yellow and blue denote %G+C content (window size of 10 000 bp, step size 1000 bp), ranging from 30% to 53% with a step of 1%, which was higher and lower than the average G+C content of Rs1, respectively. The green and red denote G+C skew $[(G - C)/(G + C)]$; (window size 10 000 bp, step size 1000 bp), ranging from -0.22 to 0.25 with a step of 0.01%, and values <0 and >0, respectively.

^a*Neptunomonas japonica* DSM 18939.

^bCharacter statistics for both symbiont genomes were similar in RAST and IMG/M.

^cIncludes both conserved hypothetical proteins (inferred homology to hypothetical proteins encoded by other genomes) and those with no inferred homology to any previously identified proteins.

^dThis value reflects the incomplete nature of the symbiont Rs2 genome, in that it is missing many of the co-localized RNA subunit genes (Supplementary Table S2).

(ANI) value of 73%, which clearly suggests they belong to different species (Konstantinidis and Tiedje, 2005; Goris *et al.*, 2007). *Neptuniibacter caesariensis*, isolated from the Mediterranean Sea, and *Neptunomonas japonica*, isolated from sediments near a sperm whale carcass off Japan, were the closest sequenced relatives based on genomic data available (Arahal *et al.*, 2007; Miyazaki *et al.*, 2008), and both shared ~67% ANI value with the *Osedax* symbiont genomes. For this reason, many traits below are compared between the *Osedax* symbionts and these related bacteria.

Evidence for a free-living lifestyle

The genomic characteristics of intracellular symbionts are greatly affected by the mode of transmission between host generations. In general, large genomes are thought to be more ecologically versatile (Konstantinidis and Tiedje, 2004), which would thus be important for an environmentally acquired symbiont that has both free-living and host-associated stages. The estimated genome sizes of the *Osedax* symbionts, larger than free-living relatives, and similar to the facultative intracellular endosymbiont *Teredinibacter turnerae* of the marine shipworm bivalve (Table 1; Yang *et al.*, 2009), indirectly suggests a possible retention of genes for both free-living and intracellular existence. Vestimentiferan tubeworms, siboglinid relatives of *Osedax*, are infected each generation with symbionts from the local environment in which the worm larvae settle (Nussbaumer *et al.*, 2006). It is not known definitively whether *Osedax* acquire symbionts in a similar manner, however, molecular and microscopic analysis did not detect symbionts in either eggs or early larval stages (Rouse *et al.*, 2008), supporting this assumption.

Both *Osedax* symbionts possess the full complement of genes necessary for flagella formation, including *fla*, *fle*, *flg*, *flh* and *fli* gene clusters, indicating the capability for movement. Similarly, the *Osedax* symbionts have a complex chemosensory system with >20 genes encoding for putative methyl-accepting chemotactic sensory genes (*mcp*s) involved in extracellular signal recognition and initiation of chemotaxis in bacteria (Wadhams and Armitage, 2004). The presence of genes responsible for motility-conferring flagella and sensing of the environment supports the assumption of a free-living stage for the *Osedax* symbionts. The large number of *mcp* genes identified in the symbionts may reflect complex associations with other organisms, as observed for many pathogens and some symbionts (~20–40 *mcp* genes is common; Dziejman *et al.*, 2002; Robidart *et al.*, 2008). However, the free-living relative *Neptunomonas japonica* also possesses a large number of *mcp* copies ($n=17$), thus it is more likely that this reflects an increased need for detection and response to dissolved organic matter at abyssal

depths, as has been observed in the genomes of many deep-sea bacterial species (Lauro and Bartlett, 2008).

Metabolic flexibility

Lack of CO₂ fixation genes supports early evidence of the heterotrophic nature of the *Osedax* symbionts and confirms their unusual divergence from the typical chemosynthetic lifestyle of all other related siboglinids (Naganuma *et al.*, 2005; Thornhill *et al.*, 2008; Hilário *et al.*, 2011). Consistent with possible exposure to variable chemical regimes, and heterotrophy, the transport profile of the *Osedax* symbionts indicates flexibility in the types of compounds brought into the cell. The genome for both symbionts is devoted to ATP-binding cassette (ABC) and TRAP-like transport genes with predicted specificity for various carbohydrates, amino acids and peptides, suggesting a broad substrate spectrum for both carbon and nitrogen gain (Table 2, Supplementary Table S4). Membrane transport, as a category, comprised 10–12% of the total number of annotated genes in the *Osedax* symbiont genomes, compared with 8% in both *N. caesariensis* and *N. japonica* (Supplementary Table S4). Notably, ~30 genes involved in ABC transport of oligo- and dipeptides were observed in the symbiont genomes, compared with <10 in both *N. caesariensis* and *N. japonica*. The symbionts have the potential to metabolize monosaccharides, sugar alcohols, fatty acids, organic acids, and in the case of symbiont Rs2, disaccharides and amino sugars (Tables 2–4). This versatility in the *Osedax* symbionts likely reflects the diversity of compounds readily available in the whale fall environment, as well as those available intracellularly. Overall, the genomic potential for monosaccharide uptake by the *Osedax* symbionts, in particular, is in stark contrast to both *N. caesariensis* and *N. japonica*, which instead have greater numbers of genes dedicated to fermentation (Table 4; Arahal *et al.*, 2007; Miyazaki *et al.*, 2008). Apparent uptake of ¹³C-labeled glucose supports the utilization of monosaccharides by *Osedax* (Table 5), however further analyses with larger sample sizes is necessary to confirm the importance of specific substrates in their overall metabolism.

Collagen is thought to be the source of nutrition for the *Osedax* symbiosis, based on consistent $\delta^{13}\text{C}$ signatures between *Osedax* tissues and the collagen-specific fraction found in bone (Goffredi *et al.*, 2005). A potential for collagen breakdown by the *Osedax* symbiosis was established by the presence of collagenase in the root tissues of individual worms (Goffredi *et al.*, 2007), although at the time it was not possible to determine whether the symbiont or host was the source of the collagenase activity. In the present study, collagenase genes were not identified in the *Osedax* symbiont genomes and instead, genes with homology to glycine

—, not identified or missing two out of three genes necessary for ABC cassette.

^aIncludes a substrate-binding protein-coding gene (no abbreviation given).

^bIndicates genes found in a contiguous operon in the *Osedax* symbionts.

^cIndicates that the ABC cassette is missing only one gene.

^dIndicates a complete cassette, with no abbreviation given.

^eAlso annotated as a ferrichrome transporter in SEED.

oxidase, proline iminopeptidase, 4'-hydroxyproline dipeptidase were identified in both symbionts. In live animal tracer experiments, ¹³C from labeled glycine (with proline amended), was taken up by the worms within 65 h of exposure (Table 5). It now seems likely, then, that collagen-derived amino acids (for example, glycine, proline and hydroxyproline) or peptides are liberated by the host, and used by the symbionts. Genes involved in proline catabolism were also identified in symbiont Rs2 by an indirect screen of bacterial mRNA transcripts from the root tissue of *Osedax frankpressi*, suggesting a role in the intact symbiosis (G. Rouse, SIO, personal communication). Additionally, in the present study, numerous copies of genes homologous to those that encode for ABC transport of both oligopeptides (OppABCD) and dipeptides (DppBCDF; Monnet, 2003) were found in the *Osedax* symbionts, arranged in 5–6 kb operon-like structures. As a symbiont, peptidolytic activity would be important if, as mentioned, the host worm provides small peptides derived from the dissolution of the collagenous bone matrix.

There appears to be similar versatility with regard to phosphate and iron acquisition by both *Osedax* symbionts. Phosphate uptake genes identified in the *Osedax* symbionts included ABC-transporters for phosphate, phosphonate and glycerol-3-phosphate (glycerol-P). By comparison, only 3 of the 17 *Oceanospirillales* relatives (Figure 3) possessed all three mechanisms. Iron uptake, which is discussed in more detail later, is also potentially accomplished via three separate mechanisms in each symbiont, including ABC transport of ferric iron and heme by both symbionts, as well as heme uptake by the Rs1 symbiont and siderophore-mediated iron uptake in symbiont Rs2 (Table 3). All of these genes were identified along operons (3–8 kb), on large contigs (11–90 kb), and included the presence of the *Fur* gene, which mediates the transcriptional regulation, via its protein product, of iron-related genes (Litwin and Calderwood, 1993). Similarly, only 2 of 17 close relatives examined possessed all three distinct mechanisms for iron uptake. This flexibility in the *Osedax* symbionts for the solubilization and acquisition of iron may reflect adaptation to both the deep-sea water column and host cytosol.

Genomic implications for intracellular life

Heterotrophic intracellular symbionts must adapt their metabolism to the available nutrients and physical conditions within the cell or in vacuoles, as is the case for the *Osedax* symbionts. A dependence on cytosolic carbon and other nutrients requires special physiological adaptations that may not be observed in closely related free-living relatives. In general, the mechanisms of nutrient uptake by intracellular bacteria are not well understood and for the *Osedax* symbionts is a situation much more analogous to that of intracellular pathogens, rather than either chemo- or photoautotrophic endosymbionts.

As mentioned, the *Osedax* symbiont genomes reveal the potential for numerous methods of iron mobilization and transport, some of which are closely linked to virulence in other bacteria. For example, genes that encode large surface exoproteins, homologous to hemolysins, were identified in both *Osedax* symbionts. The acquisition of iron from host cells, most of which is bound, is accomplished by many intracellular bacteria by the production of hemolysins (Kuhn *et al.*, 1988; Portnoy *et al.*, 1988). The direct use of heme and/or heme has also been observed in many pathogens and for *Yersinia*, *Neisseria* and *Vibrio* species, is the sole strategy for iron acquisition (Perry and Brubaker, 1979; Mickelsen and Sparling, 1981; Stoebner and Payne, 1988). Not only do both *Osedax* symbionts possess ABC-type heme transporters, but the Rs1 symbiont specifically carries the *hmu* gene cluster, which is essential for utilization of free heme, and heme-protein complexes by *Yersinia pestis* (Hornung *et al.*, 1996). Likewise, siderophores, for which coding genes were identified in the *Osedax* symbiont Rs2 genome, can also effectively scavenge iron from host iron-binding compounds. Interestingly, the siderophore transport genes observed in the Rs2 symbiont were similar (45–55% by amino acid content) to those encoding the citrate-containing siderophores petrobactin, anguibactin and vibriobactin found in many pathogenic bacteria (Griffiths *et al.*, 1984; Actis *et al.*, 1986; Koppisch *et al.*, 2005). Iron scavenging has been shown to be critically important to successful virulence and may confer the same advantage for accessing iron in intracellular beneficial endosymbionts as it does

Table 3 Select metabolic capabilities attributed to the *Osedax* symbionts Rs1 and Rs2, or both

Capabilities in bold were not observed in more than three closely related genera ($n = 10$ examined; Figure 3), and thus appear less common to the Oceanospirillales family.

^aThis gene cluster is listed as also being involved in rhamnose, or other sugar transport.

^bA single gene, *htsA*, was observed in more than four close relatives.

^cA single gene, *phnE*, was observed in five close relatives.

^dThe COG function of this gene cluster is annotated as a cobalt transporter.

^eGene clusters for capsule formation were identified in all four *Halomonas* species, as well as in 1–2 other close relatives.

in pathogens. The Candidatus Poribacteria symbiont in sponges has the genomic potential for both ferric iron and heme uptake (Siegl *et al.*, 2010), Candidatus *Endoriftia persephone*, the symbiont in tubeworms, can uptake both ferrous and ferric iron (Robidart *et al.*, 2008), whereas *Teredinibacter turnerae*, the symbiont of wood-feeding bivalves, appears to possess only a single hemin-based mechanism for iron uptake (Yang *et al.*, 2009). Until additional data is available for other beneficial

symbionts, it remains unknown whether multiple modes of iron acquisition are an adaptation broadly employed by symbionts.

In addition, genes that bypass part of the TCA cycle, including isocitrate lyase (*aceA*), malate synthase (*aceB*) and methylisocitrate lyase (*prpB*) were identified in the *Osedax* symbionts. Although observed widely in bacteria, the glyoxylate and methylcitrate cycles have been attributed to enhancement of cytosolic residence in intracellular

^{13}C -Glucose (47 mM, 18% label)	460.6	778.4
^{13}C -Ribose (17 mM, 25% label)	14.6	43.4

^aSubstrate concentrations were different between treatments.^bThe worms collected for this experiment harbored symbionts most closely related to Rs1, shown in Figure 1 (dive DR471).^cCombined root and trunk ($n = 4$). A previous study revealed trunk and root tissue to have similar $\delta^{13}\text{C}$ values within 1.0‰ (Goffredi *et al.*, 2005).

pathogens including *Mycobacterium* and *Salmonella*, presumably by allowing for rapid and efficient growth on host-produced odd-chain-length fatty acids (McKinney *et al.*, 2000; Fang *et al.*, 2005; Muñoz-Elías and McKinney 2005; Gould *et al.*, 2006; Eisenreich *et al.*, 2010). The *Osedax* symbionts possess many genes devoted to the specific degradation of branched-chain amino acids, which also results in the generation of propionyl-CoA, rather than acetyl-CoA (Muñoz-Elías *et al.*, 2006), thus increasing the necessity for the methylcitrate cycle. The observation of genes for these two TCA shunts in both *Osedax* symbionts, as well as in the marine bivalve symbiont, *Ruthia magnifica* (Newton *et al.*, 2007), suggests that they, too, may be important for intracellular life. Again, however, a more thorough comparison between heterotrophic symbionts and pathogens is critical to our understanding of the relative importance of these pathways for symbiosis.

Finally, although the *Osedax* symbionts presumably form beneficial associations, they possess genes known to be involved in attachment and colonization of eukaryotic cells. Both *Osedax*

symbionts contain *pil* genes responsible for Type IV pili formation, including pilin subunits, a prepilin peptidase, assembly and retraction ATPases, an inner membrane protein, and a secretin (Supplementary Results; Craig and Li, 2008). Similarly, they possess *imp* genes that encode Type VI pili formation, as well as the *clpB* and *vrgG* genes observed to be necessary for host cell interactions and virulence in many pathogens (Table 3; Supplementary Results; Schlieker *et al.*, 2005; Schell *et al.*, 2007; Schwarz *et al.*, 2010). Neither of the closest free-living relatives, *Neptuniibacter caesariensis* and *Neptunomonas japonica*, possess Type VI secretion systems. Genes encoding a mannose-sensitive hemagglutinin (MSHA)-like Type-IVa pilus were also identified in both symbionts and the *Osedax* Rs1 symbiont uniquely possesses a Type-IVb tight adherence (*tad*) pilus-encoding gene cluster. These pili function in surface attachment, biofilm formation and colonization and are considered a key virulence factor in *Vibrio cholerae* and other pathogenic bacteria (Chiavelli *et al.*, 2001; Dalisay *et al.*, 2006; Tomich *et al.*, 2007; O'Connell Motherway *et al.*, 2011). Both symbionts possess genes with homology

to the internalin A (*inlA*) of *Listeria monocytogenes* and *Clostridia perfringens*, which functions in adhesion and movement into host cells (Gaillard *et al.*, 1991; Lecuit *et al.*, 1997). Similarly, large genes were identified in both symbionts with homology to those that encode RTX-like toxins, which aid in membrane disruption and host cell invasion by pathogenic and symbiotic bacteria (Fullner *et al.*, 2002; Jeong *et al.*, 2005; Ruby *et al.*, 2005). Both *T. teredinibacter* and *Photorhabdus luminescens*, the symbiont of entomopathogenic nematodes, possess many similar secretion systems, adhesins and toxins, suggesting a role in mediating both adverse and beneficial interactions with eukaryotes (Ffrench-Constant *et al.*, 2000; Duchaud *et al.*, 2003; Yang *et al.*, 2009). The *Osedax* symbionts are not only suspected to infect nascent *Osedax* larvae, at a time when their immune system and developmental program might be more conducive to infection, but also to repeatedly infect adults, through their root tips, over time (Verna *et al.*, 2010). The latter scenario requires the symbionts to possess sufficient colonization mechanisms for adhesion and entry into the worms. The observed Type IV and VI secretion systems and putative virulence factors, such as internalins and toxins, may aid in this initial and repeated encounter and infection by the *Osedax* symbionts.

The intracellular symbionts in *Osedax* likely provide an essential function that enables the unusual ecology of these worms, yet we did not identify obvious genomic features that uniquely identify them as symbionts. The symbionts appear capable of *de novo* synthesis of most B vitamins, including the very long vitamin B12 synthesis pathway, as well as a capability for vitamin B12 transport (*btuCDF* genes identified in the *Osedax* symbiont Rs1 and the *btuC* gene in the Rs2 symbiont). It, thus, makes it tempting to speculate that vitamin B12 could be made and transported to the host, which is presumably incapable of its own B12 synthesis, as are all animals (Warren *et al.*, 2002). Similarly, the symbionts are capable of *de novo* synthesis of all amino acids, except asparagine and tyrosine. The intriguing presence of a large number of genes annotated as 'lysine exporter protein LysE/YggA', involved in the export of several essential amino acids, and an apparent absence of these genes in the genomes of fully sequenced relatives, suggests that they may be specifically relevant for the *Osedax* symbiosis. Presently, however, the specific role of the symbionts remains to be definitively elucidated and requires further examination using culture-dependent and -independent techniques.

Environmental niche adaptation by symbiont populations

A whale fall instantaneously creates a novel habitat that progressively changes as opportunistic

organisms exploit the massive influx of nutrients to the seafloor. These spatially heterogeneous and enriched habitats persist for varying timespans of 5 to 50 years, depending on a number of conditions (for example, depth and oxygen concentrations; Smith and Baco, 2003; Goffredi *et al.*, 2004; Braby *et al.*, 2007; Lundsten *et al.*, 2010). Many organisms, both animals and free-living microbes, tend to be stratified in space and time around the decomposing carcasses (Smith *et al.*, 2002; Goffredi *et al.*, 2004; Braby *et al.*, 2007; Goffredi *et al.*, 2008; Vrijenhoek *et al.*, 2009; Goffredi and Orphan, 2010; Lundsten *et al.*, 2010). Temporal variation also exists in relative abundances of the dominant symbiont types that infect *Osedax* (Goffredi *et al.*, 2007; Verna *et al.*, 2010). Disproportionately greater numbers of ribospecies Rs2 occur at later points in time (Salathé and Vrijenhoek, 2012). This shift occurs independently of shifts in host species composition, resulting perhaps from local adaptations to temporal changes in environmental gradients encountered by the pre-infectious 'free-living' bacteria (Verna *et al.*, 2010; Salathé and Vrijenhoek, 2012). Intra-symbiont temporal variation in this study was also indicated by genes involved in the chemotaxis pathway sequenced from *Osedax* which housed only symbiont Rs1 with identical 16S rRNA sequences, collected from 26 different worms from two sites, over a 112-month period. These genes, including *mcp3*, *mcp4*, *cheA*, *cheB* and *cheR*, differed among specimens by as much as 20% amino-acid content and clustered according to the duration of time the whale carcass was estimated to be on the seafloor (7–63 months and 59–112 months, respectively; Figure 4). It is currently not clear whether this pattern is solely derived from temporal variation of the environmental symbiont community or if there is also a certain amount of species specificity of symbiont strains involved.

Genomic differences in the metabolic and biochemical potential of Rs1 and Rs2 are similarly consistent with the hypothesis that the environment controls the symbiont populations at a given time, and that hosts primarily acquire the locally-adapted symbiont. For example, Rs2 uniquely carries genes for sulfide oxidation (*soxABDXYZ* and *molybdopterin C*), some in a contiguous 4.2-kb operon. *sox* gene sequences were similar (47–70% amino-acid content) to genes from *Neptuniibacter caesariensis*, and many other sulfide-oxidizing free-living species. Targeted PCR amplification of the *soxB* from the genomic DNA of symbiont Rs2, and not Rs1, confirmed the likely absence of these genes from the latter symbiont (Supplementary Figure S4). Advanced stages of whale fall decomposition generate significant increases in sulfide concentrations (Smith and Baco, 2003; Goffredi *et al.*, 2008) and the ability to detoxify this harmful substance should benefit Rs2 during these later stages. Rs1 and Rs2 also differ in their abilities to use carbohydrates (Tables 3 and 4). Specifically, Rs2 possesses a full complement of genes required for the uptake and metabolism of

monosaccharides (ribose), disaccharides (maltose) and amino sugars (*N*-acetylglucosamine). The fact that symbiont Rs1 may be deficient in these capabilities was indicated by the much lower tissue enrichment values when animals were exposed to ¹³C-labeled ribose (Table 5). These preliminary experiments should be repeated with larger sample sizes and consistent substrate concentrations to further confirm the distinct capabilities, or lack thereof, of each *Osedax* symbiont. The clade encompassing Rs2 also contains free-living representatives, including several found at the Deep Horizon oil spill (Figure 1; for example, HQ652516, Kessler *et al.*, 2011), similarly suggesting a broader nutritional repertoire than that of Rs1 and the others. During later stages of whale fall decomposition Rs2 may be exposed to a diverse milieu of carbon substrates, including sugars in the water column or on surfaces. Examinations of the specific changes in the availability of carbohydrates, in relation to whale fall longevity, as well as the actual occurrence of the symbionts in the environment outside the symbiosis and the biogeochemical parameters that determine their presence, are needed to test this hypothesis.

Conclusion

Despite a rise in publications on beneficial bacteria, detailed genomic information is available for relatively few intracellular endosymbionts that are newly acquired from the environment in each host generation. This endeavor is particularly relevant given our growing appreciation of the profound ways by which intimate interactions with bacteria can shape animal biology. In a recent synthesis of the top 100 fundamental questions in ecology, Sutherland *et al.* (2013) suggested that understanding the contribution of intraspecific diversity to the dynamics of mutualistic interactions, as well as the role of symbionts in maintaining host diversity, which must invariably relate to symbiont capabilities, are among the top research goals with regard to microbial ecology. Comparative genomics between closely related bacteria can reveal unique patterns of adaptation and ecological diversification. In this study, an assessment of the genomic capacity of the *Osedax* endosymbionts revealed metabolic versatility in carbon, phosphate and iron uptake strategies, mechanisms for intracellular survival, and numerous potential virulence/colonization capabilities. In the present case, and perhaps for other horizontally propagated symbioses, 'opportunistic acquisition' of locally adapted, environmental stages of the bacterial population may influence host diversity. Further genomic examinations of intracellular symbionts with free-living phases, and the elucidation of environmental controls on their temporal and spatial distributions, will establish a foundation for addressing hypotheses about the complex host-symbiont associations in marine and terrestrial environments.

Conflict of Interest

The authors declare no conflict of interest.

Acknowledgements

We thank the captain and crew of the RV *Western Flyer*, the pilots of the ROVs *Tiburon* and *Doc Ricketts*, Y-J Won for introducing us to the Chunlab and for shipboard assistance in June 2011, J Harvey and L Lundsten for shipboard support, S Johnson for support at sea and in the laboratory, as well as G Rouse (Scripps Institution of Oceanography) and VJ Orphan (California Institute of Technology) for continued professional support. We also thank the Moore Foundation for an initial attempt at sequencing the *Osedax* symbiont Rs2 genome, which, despite being aborted due to excessive host contamination, yielded early insights that informed subsequent analyses; E Allen (Scripps Institution of Oceanography) for bioinformatics assistance on the early genome attempts; K Dawson (California Institute of Technology) for ¹³C analysis of *Osedax* tissues; C Skennerton (Australian Centre for Ecogenomics, University of Queensland) for the estimates of completeness for both genomes. Funding for undergraduate students was provided by a HHMI grant to Occidental College and the Undergraduate Research Center (Academic Student Projects) at Occidental College. This project was funded primarily by a National Science Foundation grant to S Goffredi (Occidental College, IOS-0923775).
