Viral lysis of phytoplankton constrains marine primary production, food web dynamics and biogeochemical cycles in the ocean. Yet, little is known about the biogeographical distribution of viral lysis rates across the global ocean. To address this, we investigated phytoplankton group-specific viral lysis rates along a latitudinal gradient within the North Atlantic Ocean. The data show large-scale distribution patterns of different virus groups across the North Atlantic that are associated with the biogeographical distributions of their potential microbial hosts. Average virus-mediated lysis rates of the picocyanobacteria *Prochlorococcus* and *Synechococcus* were lower than those of the picoeukaryotic and nanoeukaryotic phytoplankton (that is, 0.14 per day compared with 0.19 and 0.23 per day, respectively). Total phytoplankton mortality (virus plus grazer-mediated) was comparable to the gross growth rate, demonstrating high turnover rates of phytoplankton populations. Virus-induced mortality was an important loss process at low and mid latitudes, whereas phytoplankton mortality was dominated by microzooplankton grazing at higher latitudes (>56°N). This shift from a viral-lysis-dominated to a grazing-dominated phytoplankton community was associated with a decrease in temperature and salinity, and the decrease in viral lysis rates was also associated with increased vertical mixing at higher latitudes. Ocean-climate models predict that surface warming will lead to an expansion of the stratified and oligotrophic regions of the world's oceans. Our findings suggest that these future shifts in the regional climate of the ocean surface layer are likely to increase the contribution of viral lysis to phytoplankton mortality in the higher-latitude waters of the North Atlantic, which may potentially reduce transfer of matter and energy up the food chain and thus affect the capacity of the northern North Atlantic to act as a long-term sink for CO₂.

The ISME Journal (2016) 10, 500–513; doi:10.1038/ismej.2015.130; published online 11 August 2015

Introduction

Viruses are important mortality agents for marine phytoplankton (Evans *et al.*, 2003; Tomaru *et al.*, 2004; Brussaard, 2004a; Baudoux *et al.*, 2006). Through the lysis of their autotrophic hosts, viruses regulate primary production (Suttle *et al.*, 1990) and have key roles in species competition and succession of phytoplankton populations (Gobler *et al.*, 1997; Mühling *et al.*, 2005; Haaber and Middelboe, 2009). Moreover, lysis of microbes diverts energy and biomass away from the classical grazer-mediated food web toward microbial-mediated recycling and the dissolved organic matter pool. This 'viral shunt' reduces the transfer of carbon and nutrients to higher trophic levels, while enhancing the recycling of potential growth-limiting nutrients (Fuhrman, 1999;

Wilhelm and Suttle, 1999). In this manner, viruses have major effects on nutrient cycles and energy flow in the ocean (Brussaard and Martinez, 2008; Weitz and Wilhelm, 2012). As microbial photoautotrophs are responsible for roughly half of the global annual carbon dioxide fixation and sustain the higher trophic levels in marine ecosystems (Field *et al.*, 1998), their viruses also have the potential to influence these global scale processes.

Marine virus dynamics and virus–host interactions are affected by both abiotic and biotic factors (Mojica and Brussaard, 2014), which can vary on both spatial and temporal scales. However, despite biogeographical distributions of bacteria and phytoplankton being extensively studied (Irigoiien *et al.*, 2004; Martiny *et al.*, 2006; Fuhrman *et al.*, 2008), the possible existence of biogeographical patterns in marine viral populations (and how these may vary) has received less attention (Breitbart and Rohwer, 2005; Angly *et al.*, 2006; Matteson *et al.*, 2013). For example, thermal stratification is an important factor regulating phytoplankton dynamics and ocean-climate models predict that global warming will

lead to an expansion of the stratified regions of the world's oceans (Sarmiento *et al.*, 1998; Toggweiler and Russell, 2008). Projected alterations to stratification and vertical mixing have the potential to affect the species composition (Huisman *et al.*, 2004; Mojica *et al.*, 2015), phenology (Edwards and Richardson, 2004), productivity (Gregg *et al.*, 2003; Behrenfeld *et al.*, 2006; Polovina *et al.*, 2008), size structure (Daufresne *et al.*, 2009; Hilligsøe *et al.*, 2011), nutritional value (Mitra and Flynn, 2005; Van de Waal *et al.*, 2010), abundance (Richardson and Schoeman, 2004) and biogeographical distribution (Doney *et al.*, 2012; Flombaum *et al.*, 2013; van de Poll *et al.*, 2013) of marine phytoplankton. As obligate parasites, viruses rely on their host to provide the machinery, energy and resources required for viral replication and assembly. Consequently, factors regulating the physiology, production and removal of the host are also important in governing viral dynamics (Van Etten *et al.*, 1983; Moebus, 1996; Baudoux and Brussaard, 2008; Maat *et al.*, 2014). Therefore, future changes in stratification also have the potential to affect the composition and distribution of viral assemblages associated with phytoplankton communities, and the sensitivity of marine phytoplankton populations to grazing and viral infection.

The North Atlantic Ocean offers a large-scale latitudinal gradient, with permanent stratification in the subtropics and seasonal stratification in the temperate zones (Longhurst, 2007; Jurado *et al.*, 2012). The spring phytoplankton bloom is triggered by reduced vertical mixing and the onset of seasonal stratification, owing to warming of the surface waters (Sverdrup, 1953; Huisman *et al.*, 1999; Taylor and Ferrari, 2011), and represents one of the most important biological events in the North Atlantic (Siegel *et al.*, 2002). The bloom begins in December–January at a latitude of $\sim 35^\circ\text{N}$, just north of the permanently stratified waters of the North Atlantic Subtropical Gyre and subsequently spreads across the North Atlantic throughout spring and summer, expanding northward to the Arctic waters in June (Siegel *et al.*, 2002). The spring bloom takes up large amounts of CO_2 , and owing to deep water formation at high latitudes the North Atlantic has a key role in oceanic CO_2 sequestration (Deser and Blackmon, 1993). Yet, little is known about the biogeographical patterns in viral abundances and viral lysis rates of phytoplankton across the North Atlantic, and how these may affect the transfer of the photosynthetically acquired carbon and energy to higher trophic levels. This is primarily because of a severe lack of quantitative estimates of phytoplankton losses due to viral lysis (Weitz and Wilhelm, 2012) and how these relate to changes in environmental variables.

In this study, we therefore investigate large-scale distribution patterns of the following: (i) marine viral groups and their potential hosts, and (ii) viral lysis and grazing rates of marine phytoplankton over a latitudinal gradient across the North Atlantic Ocean.

Specifically, we assess the following hypotheses: (H1) the abundances and composition of the microbial host populations (that is, bacteria and phytoplankton) vary with latitude (H1a) and are strongly affected by changes in water column stratification (H1b). (H2) The biogeographical distributions of the different viruses depend on the biogeographical distributions of their microbial host populations. (H3) Viral lysis rates of marine phytoplankton vary with latitude, affecting the relative importance of the viral shunt versus the classic grazing-mediated food web.

Materials and methods

Sampling and physicochemical variables

In July–August of 2009, 32 stations were sampled in the Northeast Atlantic Ocean during the shipboard expedition of STRATIPHYT (changes in vertical stratification and its impacts on phytoplankton communities) (Figure 1). Water samples were collected from at least 10 separate depths in the top 250-m water column using GO-flow (General Oceanics, Miami, FL, USA), 10-liter samplers mounted on an ultra-clean (trace-metal free) system equipped with CTD (Sea-Bird Electronics, Bellevue, WA, USA) with standard sensors and auxiliary sensors for chlorophyll autofluorescence (Chelsea Awuatacka MK III sensor, Chelsea Instruments, West Molesey, UK). Data from the chlorophyll autofluorescence sensor were calibrated against high-performance liquid chromatography data according to van de Poll *et al.* (2013), in order to determine the total chlorophyll *a* (Chl *a*). Samples were taken inside a 6-m clean lab for analysis of inorganic nutrients (5 ml) and flow cytometry (10 ml). Samples for dissolved inorganic nutrients (5 ml) were analyzed onboard using a Bran+Luebbe Quattro AutoAnalyzer (SEAL Analytical GmbH, Norderstedt, Germany) for dissolved orthophosphate (Murphy and Riley, 1962), nitrate and nitrite (NO_x) (Grasshoff, 1983), and ammonium (Koroleff, 1969; Helder and de Vries, 1979). Detection limits were $0.028 \mu\text{mol l}^{-1}$ for PO_4^{3-} , $0.10 \mu\text{mol l}^{-1}$ for NO_x and $0.09 \mu\text{mol l}^{-1}$ for NH_4^+ . Water samples for the modified dilution assay, to determine viral lysis and microzooplankton grazing rates on phytoplankton, were taken from the depth with maximal phytoplankton Chl *a* autofluorescence, that is, the deep chlorophyll maximum (DCM) or mixed layer (ML). All materials used for sampling water for dilution experiments were prewashed in acid (0.1 M HCl , overnight), rinsed with Milli-Q water (Veolia Water Technologies, Ede, Netherlands) (three times) and rinsed with *in-situ* water before use.

Density of seawater was expressed as σ_T values, defined as $\sigma_T = \rho(S, T) - 1000$, where $\rho(S, T)$ is the density of seawater at temperature *T* and salinity *S* measured in kg m^{-3} at standard atmospheric pressure. Temperature eddy diffusivity (K_T) data, referred to here as the vertical mixing coefficient, were

Figure 1 Bathymetric map of the stations sampled during the cruises STRATIPHYT (white circles and red diamonds) and MEDEA (green squares and black diamonds). Modified dilution assays to determine viral lysis and microzooplankton grazing rates were performed at stations indicated by the red and black diamonds. Cruise track was prepared using Ocean Data View (ODV version 4.6.5, Schlitzer, 2002).

derived from temperature and conductivity microstructure profiles measured using a SCAMP (Self Contained Autonomous Microprofiler) (Stevens *et al.*, 1999; Jurado *et al.*, 2012). The SCAMP was deployed at fewer stations (that is, 14) and to lower depths (up to 100 m) than the remainder of the data in the present study. In order to correct for this deficiency, data were interpolated using the spatial kriging function 'krig' executed in R using the 'fields' package (Furrer *et al.*, 2012). Interpolated K_T values were bounded below by the minimum value measured; the upper values were left unbounded. This resulted in estimated K_T values, which preserved the qualitative pattern and range of values previously reported (Jurado *et al.*, 2012). In addition, the depth of the ML (Z_m) was determined as the depth at which the temperature difference with respect to the surface was 0.5 °C (Levitus *et al.*, 2000; Jurado *et al.*, 2012). As shown by Brainerd and Gregg (1995), this definition of the ML provides an estimate of the depth through which surface waters have been mixed in recent days. On the few occasions where SCAMP data were not available, Z_m was determined from CTD data. Temperature profiles obtained from SCAMP and CTD measurements were compared and showed good agreement. To quantify the strength of stratification, CTD data were processed with SBE Seabird software (Sea-Bird Electronics) to calculate the Brunt–Väisälä frequency (N^2 , in $\text{rad}^2 \text{s}^{-2}$) using the Fofonoff adiabatic leveling method (Bray and Fofonoff, 1981). The Brunt–Väisälä frequency

represents the angular velocity (that is, the rate) at which a small perturbation of the stratification will re-equilibrate. Hence, it is a simple measure of the stability of the vertical stratification.

In October–November 2011, an opportunity was presented to join the MEDEA (Microbial Ecology of the Deep Atlantic) cruise, to conduct additional modified dilution experiments in the oligotrophic area of the Northeast Atlantic Ocean (Figure 1). During MEDEA, physicochemical parameters were measured from three to five depths per station within the upper 120-m water column using the same methods as for STRATIPHYT. However, no SCAMP measurements were conducted during MEDEA and ammonium concentrations were not determined. Samples for modified dilution assays were taken mostly from the DCM depth (Supplementary Table S1).

Microbial abundances

Viruses, bacteria, cyanobacteria and eukaryotic phytoplankton < 20 μm were enumerated using a Becton-Dickinson (Erembodegem, Belgium) FACSCalibur flow cytometer (FCM) equipped with an air-cooled Argon laser with an excitation wavelength of 488 nm (15 mW). Approximately 1 ml of fresh seawater was used for enumeration of phytoplankton using methods described by Marie *et al.* (2005). Phytoplankton were differentiated based on their autofluorescence properties using bivariate scatter plots of either orange (that is, phycoerythrin, present in *Synechococcus* spp.) or red fluorescence (that is, Chl *a*, present in all phytoplankton) against side scatter. Average cell size for phytoplankton subpopulations were determined by size fractionation of whole water by sequential gravity filtration through 8, 5, 3, 2, 1, 0.8 and 0.4 μm pore-size polycarbonate filters, by assuming spherical diameter ($\bar{\phi}$) of size displayed by the median (50%) number of cells retained for that cluster. In total, eight distinct phytoplankton groups were detected and sized by sequential size-fractionated gravity filtration, that is, two picoeukaryotic groups (average $\bar{\phi}$ of 1.4 and 1.5 μm , respectively), three nanoeukaryotic groups (3, 6 and 8 μm $\bar{\phi}$, respectively) and three picocyanobacteria groups (*Synechococcus* spp. of 0.9 μm $\bar{\phi}$ and ecotypes *Prochlorococcus* high light of 0.6 μm $\bar{\phi}$ in surface waters and *Prochlorococcus* low light of 0.7 μm $\bar{\phi}$ in the DCM).

Bacteria and viruses were enumerated according to Marie *et al.* (1999) and Brussaard *et al.* (2010), respectively, with modifications according to Mojica *et al.* (2014). Briefly, samples were fixed with 25% glutaraldehyde (EM-grade, Sigma-Aldrich, Zwijndrecht, The Netherlands) to a final concentration of 0.5% for 15–30 min at 4 °C, flash frozen and stored at –80 °C until analysis. Thawed samples were diluted in TE buffer (pH 8.2, 10 mM Tris HCl, 1 mM EDTA; Mojica *et al.*, 2014), stained with the nucleic acid-specific green fluorescence dye SYBR Green I (final concentration of 1×10^{-4} and 5×10^{-5} of the commercial stock concentration; Life Technologies, Bleiswijk,

The Netherlands) and incubated in the dark at either room temperature for 15 min or at 80 °C for 10 min, for bacteria and viruses, respectively. Cooled samples (5 min, room temperature) were then analyzed on the flow cytometer with the discriminator set on green fluorescence. Five distinct virus groups, labeled V1–V5, were identified based on their green fluorescence and side scatter characteristics (Figure 2). Low fluorescing viral groups, V1 and V2, are considered to be primarily dominated by phages infecting heterotrophic bacteria, although some evidence suggests that eukaryotic algal viruses can also display similar low fluorescence signatures (Brussaard and Martinez, 2008; Brussaard *et al.*, 2010). The other virus groups generally contain more algal viruses, with both pro- and eukaryotic algal viruses contributing to the V3 group, whereas the higher side scatter groups, V4 and V5, commonly represent large double-stranded DNA algal viruses (Jacquet *et al.*, 2002; Brussaard, 2004b; Baudoux *et al.*, 2006).

Redundancy analysis

We applied multivariate statistical analysis to data obtained from STRATIPHYT, to test hypotheses (H1) and (H2) put forth in the Introduction section. The analysis was performed using R statistical software (R Development Core Team, 2012) supplemented by the vegan package (Oksanen *et al.*, 2013).

First, we performed a data exploration following the protocol described in Zuur *et al.* (2010). Most phytoplankton groups distinguished by flow cytometry had limited biogeographical distributions within our study area and consequently suffered from zero inflation (for example, zeroes in >20% of the data points for almost every phytoplankton group). To avoid issues arising from zero inflation and provide good quality explanatory data, phytoplankton groups were clustered into different

categories: total picocyanobacteria (*Synechococcus*, *Prochlorococcus* high-light ecotype and *Prochlorococcus* low-light ecotype), total picoeukaryotes (picoeukaryotes I+II), total nanoeukaryotes (nanoeukaryotes I+II+III) and total phytoplankton. For hypothesis (H1), the response variables were the abundances of the bacteria and different phytoplankton groups, and total Chl *a*, whereas the explanatory variables were latitude, vertical mixing coefficient (K_T , temperature eddy diffusivity), a stratification index (N^2 , Brunt–Väisälä frequency) and temperature. For hypothesis (H2), the response variables were the virus groups V1–V5 and total viral abundance, whereas the explanatory variables were the bacteria, different phytoplankton groups, total Chl *a* and the environmental variables latitude K_T , N^2 and temperature. Virus, bacteria, phytoplankton and chlorophyll data were $\log(x+1)$ transformed, and the vertical mixing coefficient and temperature were log transformed to improve the homogeneity of variance.

Next, to obtain the most parsimonious model, data were examined for collinearity of the explanatory variables by calculating variance inflation factors using the R function *corvif* (Zuur *et al.*, 2009). In a stepwise manner, all explanatory variables with variance inflation factors >8 were removed from the model. For hypothesis (H1), variance inflation factor analysis resulted in the selection of four explanatory variables: latitude, K_T , N^2 and temperature. For hypothesis (H2), variance inflation factor analysis resulted in the selection of eight explanatory variables: picocyanobacteria (Cyano), picoeukaryotic phytoplankton (PicoEUK), nanoeukaryotic phytoplankton (NanoEUK), bacteria, Chl *a*, latitude, N^2 , K_T and temperature.

Initial scatterplots of the response and explanatory variables revealed strong linear relationships and therefore redundancy analysis (RDA) (Zuur *et al.*, 2009) was chosen over canonical correspondence analysis. RDA is a combination of multiple regression analysis and principal component analysis for multivariate data. Forward selection was applied to select only those explanatory variables that contributed significantly to the RDA model, while removing nonsignificant terms. Significance was assessed by a permutation test, using the multivariate pseudo-F as test statistic (Zuur *et al.*, 2009). A total of 9999 permutations were used to estimate *P*-values associated with the pseudo-F statistic.

RDA was based on all sampling points for which we had a complete data set of explanatory and response variables. For hypothesis (H1), this amounted to 80 samples (ranging from 0 to 225 m depth, with 4–11 depths sampled per station) from 15 stations of the STRATIPHYT cruise. For hypothesis (H2), the explanatory variable N^2 was not significant (see Results). Hence, RDA could be performed on 96 samples, as the removal of N^2 permitted the inclusion of sampling points from STRATIPHYT stations that lacked N^2 data.

Figure 2 A typical dot plot of viruses counted with flow cytometry in a water sample of the STRATIPHYT cruise. Viruses (and bacteria) were discriminated by green fluorescence versus side scatter; V1–V5 indicate the five virus groups distinguished by flow cytometry.

Modified dilution experiments

To investigate hypothesis (H3) we determined viral lysis and microzooplankton grazing rates of the different phytoplankton groups using the modified dilution assay according to Kimmance and Brussaard (2010). For both the STRATIPHYT and MEDEA cruises, experiments were conducted onboard, using water samples obtained from those depths where Chl *a* autofluorescence was maximal (that is, DCM or ML). Natural seawater, gently passed through a 200- μm mesh to remove mesozooplankton (while retaining microzooplankton), was combined with 0.45 μm diluent or 30 kDa ultrafiltrate in proportions of 100%, 70%, 40% and 20%, to gradually decrease the mortality impact with increasing dilution (Supplementary Figure S1a). The 0.45 μm filtrate, prepared with the goal of removing the microzooplankton grazers, was achieved by gravity filtration of natural seawater through a 0.45- μm Sartopore capsule filter with a 0.8- μm prefilter (Sartopore 2300, Sartorius Stedim Biotech, Göttingen, Germany). The 30-kDa ultrafiltrate, prepared to remove grazers and viruses, was generated by tangential flow filtration using a polyethersulfone membrane (Vivaflow 200, Sartorius Stedim Biotech, Göttingen, Germany). All experiments were performed in triplicate in 1-liter clear polycarbonate bottles. After preparation of the two parallel dilution series (12 bottles each), a 3-ml subsample was taken and phytoplankton was enumerated by FCM as specified previously. The bottles were then incubated for 24 h in an on-deck flow-through seawater incubator at *in situ* temperature and light (using neutral density screen) conditions. After the 24-h incubation period, a second FCM phytoplankton count was executed and the resulting growth rate for each phytoplankton group determined. Dual measurements of viral lysis and grazing rates were obtained for all phytoplankton groups, except for *Prochlorococcus* high light, which was largely absent from the sampled depths.

The microzooplankton grazing rate was estimated from the regression coefficient of the apparent growth rate versus fraction of natural seawater for the 0.45- μm series, whereas the combined rate of viral-induced lysis and microzooplankton grazing was estimated from a similar regression for the 30-kDa series (Supplementary Figures S1b and c) (Baudoux *et al.*, 2006; Kimmance and Brussaard, 2010). A significant difference between the two regression coefficients (as tested by analysis of covariance) indicates a significant viral lysis rate. Phytoplankton gross growth rate (μ_{gross} , in the absence of grazing and viral lysis) was derived from the y intercept of the 30-kDa series regression.

The viral lysis and grazing rates were analyzed with a two-way analysis of variance with type II sum of squares, to assess differences between the two sources of mortality (viral lysis versus grazing) and among the phytoplankton groups (*Synechococcus*, *Prochlorococcus* low light, total picoeukaryotes and

total nanoeukaryotes). Homogeneity of variance was confirmed by Levene's test and *post-hoc* comparison of the means was based on Tukey's honest significant difference test using SPSS version 22.0 (IBM Corp., Armonk, NY, USA). Potential relationships between biological parameters obtained from the modified dilution assays (for example, phytoplankton abundance, μ_{gross} , viral lysis and grazing rates) and environmental parameters were examined by Spearman's rank correlation coefficient. Probability values were adjusted with Holm's correction for multiple hypothesis testing using the *corr.p* function of psych (Revelle, 2014) implemented in R (R Development Core Team, 2012). The correlation analysis was performed on the complete data set ($n = 105$) with a significance level (α) of 0.05.

Results

During both the STRATIPHYT and MEDEA cruise, the North Atlantic was characterized by a strong temperature-induced vertical stratification resulting in very low concentrations of dissolved inorganic nitrogen and phosphorus in the upper 50–100 m water column at latitudes south of 45°N (Figures 3a–g and Supplementary Figure S2). Toward the north, stratification weakened, slightly relaxing nutrient limitation in the upper 50 m surface layer.

For both cruises, pico-sized phytoplankton ($< 2 \mu\text{m}$ Ø) accounted for more than 95% of the total phytoplankton $< 20 \mu\text{m}$ enumerated by FCM. South of 45°N, both total phytoplankton abundance (up to $1.6 \pm 0.4 \times 10^5$ cells per ml) and Chl *a* (Figure 3g and Supplementary Figure S2e) were maximal between 30 and 100 m depth, characteristic of a DCM. Cyanobacteria were the most abundant members of the phytoplankton community in this southern region (Figure 4a) and consisted mainly of *Prochlorococcus* high light and *Prochlorococcus* low light (Supplementary Figures S3a and b). The DCM shallowed with latitude, giving over to a surface maximum north of 45°N, marking the northern boundary of the oligotrophic areas (defined by Chl *a* concentrations $< 0.07 \text{ mg Chl per m}^3$; Polovina *et al.*, 2008). Cyanobacterial abundance decreased with the loss of the DCM and disappearance of *Prochlorococcus* spp. north of 45°N (Figure 4a and Supplementary Figures S3a and b). However, the cyanobacteria *Synechococcus* spp. showed highest abundances in the most northern stations, beyond 56°N, where they numerically dominated the photosynthetic community $< 20 \mu\text{m}$ (Supplementary Figure S3c). Picoeukaryotic and nanoeukaryotic phytoplankton were relatively abundant in the DCM between 38°N and 45°N, and reached maximal abundances in the surface waters of the stations north of 54°N (Figures 4b and c, and Supplementary Figures S3d–h). Bacterial abundance was maximal in the surface waters of the most northern stations (Figure 4d).

Figure 3 Latitudinal and depth distribution of (a) temperature, (b) σ_t , (c) temperature eddy diffusivity (K_T), (d) Brunt–Väisälä frequency (N^2), (e) inorganic phosphorus, (f) NO_x (nitrate+nitrite) and (g) Chl a concentrations measured during STRATIPHYT. Black dots indicate sampling points, yellow dots indicate ML depth (Z_m) and red dots indicate the sampling depths for modified dilution assays. Figure panels were prepared using Ocean Data View (ODV version 4.6.5, Schlitzer, 2002).

The five virus groups showed distinct biogeographical distributions (Figures 4e–i). Although V1 and V2 viruses were the numerically dominant virus groups in the DCM of the strongly stratified waters below 45°N, they were even more abundant in the top 50 m of the weakly stratified waters at latitudes above 45°N (Figures 4e and f). Conversely, V3 viruses reached their highest abundances between 30 and 100 m depth in the DCM of stratified waters south of 45°N (Figure 4g). V4 and V5 viruses were present throughout the latitudinal range, but V4 reached its maximum abundance in the subsurface waters located between latitudes 40–45°N (Figure 4h) and V5 had its highest abundance in the upper 50 m surface waters in the weakly stratified waters at the higher latitudes (Figure 4i).

The hypothesis (H1) that abundances and composition of the microbial host populations (for example, bacteria and phytoplankton) vary with latitude (H1a) and are strongly affected by changes in water column stratification (H1b) is confirmed by the RDA results.

Forward selection revealed that latitude and the stratification variables K_T , N^2 and temperature all contributed significantly to the RDA model (Table 1). The results are presented in an RDA triplot (Figure 5a). The first two axes in the RDA triplot explained 27% and 4% of the variation in the data, respectively. The concentrations of bacteria, cyanobacteria, picoeukaryotic and nanoeukaryotic phytoplankton were all positively correlated with K_T and N^2 . The strong positive correlation between picoeukaryotes and N^2 is particularly noteworthy, indicating that picoeukaryotes reached their highest concentrations at or near the pycnocline. In comparison with the other species groups, cyanobacteria showed a relatively strong correlation with temperature and nanoeukaryotes a relatively strong correlation with latitude.

RDA was also applied to investigate hypothesis (H2) that the biogeographical distributions of the viruses depend on the biogeographical distributions of their hosts. Forward selection revealed that

Figure 4 Biogeographical distributions of phytoplankton (a–c), bacteria (d) and virus groups (e–i) across the Northeast Atlantic Ocean based on flow cytometry counts obtained during the STRATIPHYT cruise. Abundances are expressed in (a–c) cells per ml, (d) bacteria per ml and (e–i) viruses per ml. Black dots indicate sampling points, yellow dots indicate ML depth (Z_m) and red dots indicate the sampling depths for modified dilution assays. Graphs were prepared with Ocean Data View (ODV version 4.6.5, Schlitzer, 2002).

Table 1 Significance of the selected explanatory variables in the RDA correlation triplots (see Figure 5a and b)

Explanatory variable	AIC*	Pseudo-F	P-values
<i>Host populations (H1)</i>			
K_T	103.5	33	0.005
Temperature	95.4	10.4	0.005
Latitude	79.7	18.9	0.005
N^2	71.1	10.6	0.005
<i>Virus populations (H2)</i>			
Bacteria	89.5	135.0	0.005
PicoEUK	71.7	21.4	0.005
NanoEUK	64.8	8.9	0.005
Temperature	58.5	8.3	0.005
Cyano	54.1	6.1	0.005
Latitude	52.9	3.1	0.025

Abbreviations: AIC, Akaike Information Criterion; NanoEUK, nanoeukaryotic; PicoEUK, picoeukaryotic; RDA, redundancy analysis. The explanatory variables were selected by forward selection based on the pseudo-F statistic, using 9999 permutations to assess their significance. Total variation explained by the RDA models was 57% and 75%, respectively.

latitude, temperature and the four different potential host groups contributed significantly to the RDA model (Table 1), whereas the environmental variables K_T , Chl *a* and N^2 (pseudo-F = 1.1, 0.8 and 0.2; P = 0.39, 0.53 and 0.91, respectively) did not. The first two axes of the RDA triplot (Figure 5b) explained 51% and 3% of the variation in the data, respectively. In line with expectation, the RDA

triplet shows that the biogeographical distribution of V1 viruses was tightly coupled to the distribution of total bacterial abundance (Figure 5b). The distribution of V2 viruses was correlated with total picoeukaryotic phytoplankton abundance, whereas the distribution of V3 viruses was strongly correlated with total picocyanobacterial abundance. Furthermore, distributions of V4 and V5 viruses were associated with high abundances of nanoeukaryotic phytoplankton and bacteria (Figure 5b).

To assess hypothesis (H3), we quantified the contributions of viral lysis and grazing to the mortality of the different phytoplankton groups by conducting 34 modified dilution assays across the North Atlantic during the two cruises (Figure 1 and see Supplementary Tables S1 and S2 for details). We first tested whether the modified dilution assays themselves had any undesirable side effects on phytoplankton performance. In general, we found no associated reduction in growth rate for any of the phytoplankton groups in the 20% fraction of the 30Ka series, where potential enhanced nutrient limitation would be greatest due to reduced remineralization (as a result of removal of bacteria and grazers). Furthermore, the photosynthetic capacity remained high for all dilutions (F_v/F_m = 0.6).

Viral lysis rates varied from 0 to 1.05 per day (Supplementary Figure S2). Two-way analysis of variance of the mortality rates revealed a significant main effect of the phytoplankton groups

Figure 5 RDA correlation triplot describing (a) the biogeographical distribution of potential microbial hosts (response variables, in red) in relation to environmental variables relevant to stratification (explanatory variables, in blue) and (b) the biogeographical distributions of the viruses (response variables, in red) in relation to latitude and the biogeographical distributions of their hosts (explanatory variables, in blue) using data obtained during the STRATIPHYT cruise. Symbols represent individual sampling points ($n=80$ and 96 in **a** and **b**, respectively), where closed squares represent sampling points at stations with a DCM and open squares represent sampling points at stations without a DCM. The DCM was defined by the presence of a subsurface peak in the vertical profile of Chl *a* autofluorescence, which is a common feature of vertically stratified oligotrophic waters. All explanatory variables in the triplot are significant (Table 1). Total variation explained by the RDA models in **a** and **b** was 57% and 75%, respectively.

Figure 6 Grazing and viral lysis rates of the different phytoplankton groups. Grazing and viral lysis rates were determined using the modified dilution assay. The phytoplankton groups include *Synechococcus* (Syn, sample size $N=19$), low-light-adapted *Prochlorococcus* (Prochl LL, $N=13$), picoeukaryotes (Pico I–II, $N=45$) and nanoeukaryotes (Nano I–III, $N=28$). High-light-adapted *Prochlorococcus* was largely absent at the depths sampled for the modified dilution assays. Error bars S.E. Bars with different letters are significantly different ($P<0.05$), as tested by two-way analysis of variance followed by *post-hoc* comparison of the means using Tukey's honest significant difference.

($F_{3,188}=4.761$, $P=0.003$), whereas the main effect of the mortality source (grazing vs viral lysis) ($F_{1,188}=2.316$, $P>0.05$) and the interaction term ($F_{3,188}=0.115$, $P>0.05$) were both nonsignificant. In other words, viral lysis rates were comparable to microzooplankton grazing rates for all phytoplankton groups measured (Figure 6), demonstrating that virus-mediated lysis contributed to approximately half of the total phytoplankton mortality. However, mortality rates differed between the phytoplankton groups. The mortality rates of nanoeukaryotic and picoeukaryotic phytoplankton were not significantly different, and these two groups demonstrated the

highest average viral lysis rates of 0.23 and 0.19 per day and grazing rates of 0.27 and 0.21 per day, respectively (Figure 6). *Synechococcus* and *Prochlorococcus* experienced significantly lower mortality rates compared with the nanoeukaryotes, with viral lysis rates of 0.14 per day and grazing rates of 0.13 per day.

Total mortality rates of the specific phytoplankton groups ranged from 0.01 to 1.20 per day and were in balance with gross growth rates (Figure 7a), emphasizing fast turnover of the photoautotrophic production. Moreover, our data show a remarkable reduction in the ratio of viral lysis rates to microzooplankton grazing rates (V:G) at higher latitudes ($>56^{\circ}\text{N}$) (Figure 7b). This switch from a viral lysis-dominated to a grazing-dominated plankton community was consistent across different phytoplankton groups (Figure 7b). The pattern is corroborated by a significant negative correlation of V:G with latitude and a significant positive correlation with temperature and salinity (Table 2). Similarly, viral lysis rates but not the grazing rates showed a significant negative correlation with latitude and K_T , and positive correlation with temperature and salinity, suggesting that the reduction in V:G was due to decreased viral lysis rates at higher latitudes (Table 2).

Discussion

Our results demonstrate distinct biogeographical distributions of different virus groups and their potential host microbial populations across the North Atlantic Ocean (Figure 4). Metagenomic analyses of marine viral assemblages suggest that most viruses are widely dispersed across different oceanic regions (Angly *et al.*, 2006), providing a seeding community for recruitment once the

Figure 7 The contribution of viral lysis to phytoplankton mortality. **(a)** Relationship between the total loss rate (grazing + viral lysis) and gross growth rate of the seven phytoplankton groups ($<20\ \mu m$). The black line indicates a 1:1 relationship. **(b)** Ratio of viral lysis to microzooplankton grazing rates for each of the seven phytoplankton groups ($<20\ \mu m$) distinguished by flow cytometry, as function of latitude. Rates were obtained by the modified dilution technique during the STRATIPHYT (red symbols) and MEDEA (black symbols) cruises. High-light-adapted *Prochlorococcus* were not included, as they were largely absent at the depths sampled for the modified dilution assays. Dotted line indicates a 1:1 relationship of viral lysis to grazing.

environmental conditions turn favorable (Breitbart and Rohwer, 2005; Suttle, 2007; Thingstad *et al.*, 2014). Therefore, the classical tenet of ‘all microbes are everywhere, but the environment selects’ (Baas Becking, 1931; de Wit and Bouvier, 2006) is likely to apply to marine viruses. Accordingly, large-scale biogeographical variation in viral composition across the oceans is probably not caused by dispersal limitation but largely due to spatial variation in environmental conditions (Figure 5a). In particular, in agreement with hypothesis (H1) and (H2), our results show that the observed biogeographical distributions of marine viruses across the North Atlantic are strongly associated with the distributions of bacteria and phytoplankton that serve as their main hosts (Figure 5b). The large-scale distributions of these host species are in turn dependent

on the latitudinal gradient from warm permanently stratified waters in the subtropical North Atlantic to colder seasonally stratified waters at higher latitudes (Figure 5a).

Yang *et al.* (2010) described a correlation between V3 viruses and picophytoplankton (including picocyanobacteria and picoeukaryotes) in the Pacific Ocean, with highest V3 virus abundances in tropical and subtropical waters. Our results show that the distribution of V3 viruses is closely related to the distribution of picocyanobacteria (*Prochlorococcus* and *Synechococcus*) (Figure 5b), indicating that the cluster of V3 viruses contains many cyanophages, which is in line with previous observations that cyanophages are particularly widespread in the (sub)tropical oceans (Suttle and Chan, 1994; Wilson *et al.*, 1999; Angly *et al.*, 2006). In contrast, the distribution of V2 viruses appears to be linked to picoeukaryotic phytoplankton and both the V2 viruses and picoeukaryotic phytoplankton are abundant at mid and high latitudes (Figures 4b and f, and Figure 5b). Furthermore, our observation that V4 and V5 viruses are correlated to nanoeukaryotic phytoplankton (Figure 5b) corroborates earlier studies documenting similar FCM signatures for viruses infective against haptophytes (Jacquet *et al.*, 2002; Brussaard, 2004b; Baudoux *et al.*, 2006).

The fate of primary production has important implications for the ecology and biogeochemical recycling of marine food webs. Estimates of viral lysis rates of natural phytoplankton populations remain scarce, and consequently the importance of viruses in comparison with other loss factors remains unclear. Rates of viral-mediated mortality for *Synechococcus* (that is, 0.03–0.49 per day), picoeukaryotic phytoplankton (that is, 0–0.81 per day) and nanoeukaryotic phytoplankton (that is, 0–1.05 per day) were comparable to the ranges reported in the literature (Baudoux *et al.*, 2007, 2008; Evans and Brussaard, 2012; Tsai *et al.*, 2012). The viral lysis rates of *Prochlorococcus* (that is, 0.02–0.57 per day) presented here were higher than the maximal 0.06 per day reported thus far (Baudoux *et al.*, 2007). The typical set-up of the modified dilution assay (that is, two parallel series, four dilutions and three replicates) lacks the sensitivity required to detect significance of viral lysis rates when rates are very low (Evans *et al.*, 2003; Kimmance *et al.*, 2007; Baudoux *et al.*, 2008). Hence, we note that estimates of viral lysis rates <0.1 per day should be interpreted with caution. To improve sensitivity of the method at low viral lysis rates, more replicates should be used.

Among the different phytoplankton groups, *Synechococcus* and *Prochlorococcus* experienced the lowest average viral lysis rates (that is, 0.14 per day) (Figure 6). Considering the dominance of cyanophages and their hosts, the low viral mortality may seem surprising (Suttle and Chan, 1993; Wang *et al.*, 2011). However, *Synechococcus* and *Prochlorococcus* populations display high genotypic diversity and have the ability to develop resistance against

viral infection (Waterbury and Valois, 1993; Scanlan and West, 2002), which could potentially reduce the impact of viral-induced mortality of these phytoplankton groups.

Virus-mediated lysis was responsible for approximately half of the total phytoplankton mortality in all four phytoplankton groups that we investigated, and comparable in magnitude to the mortality rate exerted by microzooplankton grazing (Figure 6). Total mortality of phytoplankton populations was in balance with gross growth (Figure 7a), indicating fast turnover of the photoautotrophic production within the North Atlantic Ocean. These results emphasize the need for the incorporation of viral lysis into ecosystems models (Franks, 2001; Keller and Hood, 2011; Keller and Hood, 2013). Moreover, our results support hypothesis (H3) that viral lysis rates vary with latitude, and point at a striking reduction in the ratio of viral lysis rates to grazing rates of marine phytoplankton at higher latitudes (Figure 7b). Although this observation might be a local or seasonal phenomenon, our findings are consistent with a smaller-scale study in the North Sea (Baudoux *et al.*, 2008), which reported low viral lysis rates of picophytoplankton in offshore waters above 55°N. Furthermore, data from the Southern Ocean point at low viral lysis rates of phytoplankton over a relatively broad geographic range from at least 43°S to 70°S on the southern hemisphere (Evans and Brussaard, 2012). This suggests that low viral lysis rates at higher latitudes are not unique for our data set, but may represent a global pattern.

The underlying causes for the reduction in viral lysis rates with latitude remain unclear. Our results reveal a positive relationship between temperature and viral lysis rates of marine phytoplankton. Although temperature has been shown to regulate viral infection of marine phytoplankton (Cottrell and Suttle, 1995; Nagasaki and Yamaguchi, 1998), evidence that

temperature affects viral production rates is thus far largely restricted to bacterial hosts (Matteson *et al.*, 2012; Mojica and Brussaard, 2014). Vertical stratification represses turbulence and reduces ML depth, thereby determining the general availability of light and nutrients to phytoplankton in the ocean (Behrenfeld *et al.*, 2006; Huisman *et al.*, 2006). These factors have been shown to be important factors regulating the production of viruses in phytoplankton hosts (Van Etten *et al.*, 1983; Bratbak *et al.*, 1998; Jacquet *et al.*, 2002; Maat *et al.*, 2014). Yet, we did not find a significant association between viral lysis rates and nutrient concentrations, host abundance or growth rate in our data (Table 2). In addition, viral lysis rates declined with latitude despite the latitudinal increase in total virus abundance, as well as increases in V1 and V2 viruses (Figure 4 and Supplementary Table S3). An exception is the decline of the V3 viruses with latitude (Figure 4g and Supplementary Table S3), which was due to the dominance of their picocyanobacterial hosts in the (sub)tropical southern region. Metagenomic analysis has revealed that lysogeny and prophage-like sequences are common in the Arctic Ocean (Angly *et al.*, 2006). If this is a more general feature at higher latitudes, it may reduce the lytic viral lysis rates measured by the dilution assay. However, evidence for lysogeny in photoautotrophs is mostly restricted to prokaryotes (Paul, 2008). Consequently, lysogeny would not fully explain the low viral lysis rates at higher latitudes for eukaryotic phytoplankton populations. An alternative explanation might be that latitudinal changes in phytoplankton species composition result in more virus-resistant phytoplankton species at higher latitudes; however, we have no evidence to support this. We speculate that removal or inactivation rates of marine viruses by transparent exopolymer particles might be higher at the higher latitudes (Brussaard *et al.*, 2005b; Mari *et al.*, 2007). Transparent exopolymer particle concentrations have been found to

be correlated to phytoplankton biomass, photosynthetic activity and bacterial production (Claquin *et al.*, 2008; Ortega-Retuerta *et al.*, 2010), which were highest in the northern latitudes of our study (see also van de Poll *et al.*, 2013). As fluid shear is one of the primary factors controlling aggregation in pelagic systems (Jackson, 1990; Malits and Weinbauer, 2009), the increase of K_T with latitude might have promoted higher aggregate formation and increase the potential for viral (temporary) inactivation rates at higher latitudes.

Owing to deep water formation, the North Atlantic is key to ocean circulation and global climate, absorbing ~23% of the global anthropogenic CO₂ emission (Sabine *et al.*, 2004). Several studies predict that global warming will result in a stronger temperature stratification in the North Atlantic Ocean (Sarmiento, 2004; Polovina *et al.*, 2008), accompanied by changes in phytoplankton community structure, as oligotrophic regions of the ocean expand northwards (Flombaum *et al.*, 2013; Mojica *et al.*, 2015). This in turn will result in alterations to virus community structure, as virus populations respond to changing host distributions. Currently, grazing dominates phytoplankton mortality at higher latitudes, whereas the contribution of viral lysis is relatively small. However, our results indicate that warming of the surface layers will shift the ecosystem at high latitudes toward a more viral-lysis-dominated system. The partitioning of photosynthetic carbon through these different pathways (that is, grazing versus cell lysis) has important implications for ecosystem function as each pathway differentially affects the structure and functioning of pelagic microbial food webs. Grazing transfers carbon, nutrients and energy to higher trophic levels, thereby increasing the overall efficiency and carrying capacity of the ecosystem. In addition, the production of fecal pellets by mesozooplankton is responsible for much of the carbon transported out of the euphotic zone into the deeper ocean (Ducklow *et al.*, 2001). Viral lysis redirects carbon and energy away from larger organisms toward the microbial loop, and thereby rapidly returns most of the organic carbon fixed by phytoplankton into the surface layer (Fuhrman, 1999; Wilhelm and Suttle, 1999; Brussaard *et al.*, 2005a; Weitz and Wilhelm, 2012). A more prominent role of viral lysis in the northern North Atlantic would thus markedly reduce biological carbon export into the ocean's interior in one of the key areas of global carbon sequestration, reducing the ocean's capacity to function as a long-term sink for anthropogenic carbon dioxide.
