Subsurface microbial communities comprise a significant fraction of the global prokaryotic biomass; however, the carbon metabolisms that support the deep biosphere have been relatively unexplored. In order to determine the predominant carbon metabolisms within a 3-km deep fracture fluid system accessed via the Tau Tona gold mine (Witwatersrand Basin, South Africa), metagenomic and thermodynamic analyses were combined. Within our system of study, the energy-conserving reductive acetyl-CoA (Wood-Ljungdahl) pathway was found to be the most abundant carbon fixation pathway identified in the metagenome. Carbon monoxide dehydrogenase genes that have the potential to participate in (1) both autotrophic and heterotrophic metabolisms through the reversible oxidation of CO and subsequent transfer of electrons for sulfate reduction, (2) direct utilization of H₂ and (3) methanogenesis were identified. The most abundant members of the metagenome belonged to *Euryarchaeota* (22%) and *Firmicutes* (57%)—by far, the highest relative abundance of *Euryarchaeota* yet reported from deep fracture fluids in South Africa and one of only five *Firmicutes*-dominated deep fracture fluids identified in the region. Importantly, by combining the metagenomics data and thermodynamic modeling of this study with previously published isotopic and community composition data from the South African subsurface, we are able to demonstrate that *Firmicutes*-dominated communities are associated with a particular hydrogeologic environment, specifically the older, more saline and more reducing waters.

The ISME Journal (2016) 10, 730–741; doi:10.1038/ismej.2015.150; published online 1 September 2015

Introduction

For over two decades, scientists have been characterizing the geochemistry and biological composition of the subsurface biosphere to depths as great as 3.6 km (Borgonie *et al.*, 2011). These investigations have revealed that in sub-seafloor sedimentary environments, the microbial abundance appears to be positively correlated with total organic carbon (TOC) concentration (0.4–20 mol kg⁻¹) (Lipp *et al.*, 2008). In continental groundwaters and petroleum reservoirs, the microbial abundance and activity are related to proximity to interfaces with organic-rich strata (Chapelle and Lovley, 1990; Krumholz *et al.*, 1997; Bennett *et al.*, 2013). Within continental flood basalts or granitic intrusions, however, autotrophic communities relying upon dissolved inorganic carbon (DIC)

may have the dominant role (Stevens and McKinley, 1995; Pedersen, 1997). The low TOC (0.01–0.1 mol kg⁻¹) (Silver *et al.*, 2012), dissolved organic carbon (DOC) (~400 µM) and organic acid (~40 µM) concentrations of deep fracture water at the Witwatersrand Basin (Onstott *et al.*, 2006) call into question whether the subsurface microbial communities residing in these fractures are supported by these limited DOC pools or by the larger pools of alternative carbon sources such as biogenic or abiogenic CH₄ (~20 mM), abiogenic C₂₋₄ hydrocarbons (~500 µM) or DIC (DIC averaging 800 µM) (Kieft *et al.*, 2005; Onstott *et al.*, 2006; Sherwood Lollar *et al.*, 2006). Thus far, it has been shown that some of the subsurface microbial communities are sustained by radiolytically derived H₂ and sulfate (Lin *et al.*, 2006b; Chivian *et al.*, 2008). Obvious signatures of biodegradation of the abiogenic hydrocarbon pool, such as elevated isobutane to normal butane ratios (Ehrenberg and Jakobsen, 2001), are not apparent (Onstott *et al.*, 2006).

Of the many biodiversity studies of fracture water samples that were based on 16S ribosomal RNA

(rRNA) genes, one horizontal borehole located at 2.8 km below the surface (kmbls) in the Mponeng gold mine (MP104) was found to be comprised almost entirely (>99%) of a sulfate reducing chemoautolithotrophic firmicute, '*Candidatus Desulforudis audaxviator*' (Chivian *et al.*, 2008). The subsurface residence time of the bulk fracture water of MP104 was on the order of tens of Ma and the $\Delta^2\text{H}_{\text{H}_2\text{-H}_2\text{O}}$ geothermometry suggested that the fracture water originated from a depth of 4.2 kmbls (Lin *et al.*, 2006b). Other fracture water sites, ranging in depth from 0.6 to 3.2 kmbls and distributed over 300 km across the Basin, were found to contain assemblages of bacteria primarily consisting of *Proteobacteria*, *Firmicutes*, and, occasionally, a minor portion of *Euryarchaeota* based on the analyses of 16S rRNA genes (Takai *et al.*, 2001; Baker *et al.*, 2003; Moser *et al.*, 2003; Onstott *et al.*, 2003; Kieft *et al.*, 2005; Gihring *et al.*, 2006; Lin *et al.*, 2006a; Silver *et al.*, 2010; Davidson *et al.*, 2011; Magnabosco *et al.*, 2014). The surprisingly low to no observed archaeal 16S rRNA genes, the low TOC and DOC concentrations, and the low porosity (0.5% matrix, 0.01% fracture) of the Witwatersrand Basin sites distinguishes them from the more prominent archaeal communities often reported to inhabit the shallower, higher TOC bearing, higher porosity (50–90%) sub-seafloor sediments (Biddle *et al.*, 2006). Instead, the carbon cycling pathways used in the TOC- and DOC-poor Witwatersrand Basin fluids may be more similar to the SLiME communities of the deep Columbia River basalt aquifer (Stevens and McKinley, 1995), the planktonic microbial communities found within the fracture water of the Proterozoic granite in the Fennoscandian Shield (Pedersen, 1997) and autotrophic communities of the Tablelands serpentinite (Brazelton *et al.*, 2012).

A recent reevaluation of protein turnover times in the deep subsurface derived from the D/L aspartic acid racemization ratio estimated the maximum protein turnover times for the Witwatersrand Basin microbial communities to be 1–2 years (Onstott *et al.*, 2014). This finding indicates that the deep crustal biosphere is metabolically more active than previously thought, so much so that the low DOC concentrations in the Witwatersrand Basin fracture water would be depleted in $\sim 10^3$ years. Given the voluminous size of the habitable, yet carbon poor, regions of the deep continental crust and the previous estimates of subsurface microbial turnover times ($1\text{--}2 \times 10^3$ years; Whitman *et al.*, 1998), the deep continental subsurface microbial carbon metabolism requires reevaluation from an interdisciplinary perspective. Here, we report the first integration of metagenomic analyses with traditional geochemical estimates of metabolic activity in the Witwatersrand Basin and the insight gained into the carbon metabolism of microbial communities inhabiting the deep, organic carbon-poor terrestrial subsurface.

Materials and methods

Geological setting

A sub-horizontal, diamond drilled borehole (TT107) ~ 100 m in length located on level 107 (depth = 3048 mbls) of AngloGold Ashanti's Tau Tona Au Mine was sampled. The borehole intersects a fluid-filled fracture associated with the contact between the Witwatersrand Supergroup quartzite and Jeans Dyke and was sampled for metagenomic and geochemical analyses.

Sampling

Before sampling, fracture water and gas was allowed to flow from the sampling borehole to displace any potential contaminants introduced during borehole drilling. A stainless steel manifold with control valves was connected to the borehole, and PTFE tubing was attached to the ball valves on the sides of the manifold. Temperature, pH, conductivity and reduction potential (Eh) were measured from the water with handheld probes (Hanna Instruments, Carrollton, TX, USA), and dissolved O_2 , H_2O_2 , Fe(II), total Fe and sulfide were measured using field test kits (Chemetrics Inc., Calverton, VA, USA). In order to obtain sufficient biomass for sequencing, an autoclaved $0.2\text{ }\mu\text{m}$ pleated GE Memtrex NY (MNY) filter cartridge (cat. no. MNY921AAS; 25 cm in length) was placed in a stainless steel casing and attached to the steel manifold. The filter was left to accumulate biomass for 13 days at an initial flow rate of 4 l min^{-1} . On the 13 day, the filter was retrieved from the mine, stored on blue ice and transported back to the field station at the University of Free State where it was stored at -80°C . In total, 110 950 l of water had passed through the massive filter, which based on cell count-derived concentrations of 280 cells ml^{-1} (Simkus *et al.*, 2015), accounts for the accumulation of approximately 3.1×10^{10} cells. The filter was transported back to Princeton using a MVE ZC 20/3V vapor shipper and stored at -80°C until further processing.

Free energy flux

Samples for cation and anion analysis were collected using the protocols described in Lau *et al.* (2014). Mineral solubility, dissolved species activity, partial pressures and free energy of microbial reactions were calculated using the geochemical modeling program, The Geochemist's Workbench version 8.0 (Bethke, 2008). In order to elucidate whether or not the microorganisms are maintaining autotrophic, mixotrophic or heterotrophic lifestyles, we analyzed the steady-state free energy flux (FEF; Onstott, 2004) of 47 energy-yielding redox reactions to test the hypothesis that the more favorable the reaction, the more likely it would be to proceed within the biological community, if the necessary protein-encoding genes (PEGs) for a given metabolic pathway were present in the metagenome.

The steady-state FEF of a planktonic microorganism suspended in an aqueous solution was calculated using Geochemist's Workbench V8 Professional (Bethke, 2008) and the following relationship,

$$\text{Free Energy Flux (kJ cell}^{-1} \text{ s}^{-1}) = 4\pi rDC\Delta G \quad (1)$$

where r is the average radius of a cell (cm) and assumed to be 7.5×10^{-5} cm, D is the effective diffusion constant ($\text{cm}^2 \text{ s}^{-1}$) of the limiting reactant corrected for the *in situ* temperature (Cussler, 2009), C is the concentration of the limiting reactant (mol cm^{-3}) and ΔG is the *in situ* Gibbs-free energy of the limiting reactant (kJ mol^{-1}). For microbial redox reactions that involve sessile microorganisms and a hard mineral phase (for example, $\text{Fe}(\text{OH})_3$ and pyrolusite), the effective diffusion constant (D_{eff}) of the electron donor was adjusted according to the following equation,

$$D_{\text{eff}} = D \frac{\phi \times \delta}{\tau^2} \quad (2)$$

where ϕ is porosity of the hard mineral phase, τ is tortuosity and δ is constrictivity. For the purpose of this study, the porosity of the Witwatersrand Basin rock units is $\sim 0.5\%$ (Silver *et al.*, 2012), $\delta = 1$, and $\tau = 2.59$ (Takahashi *et al.*, 2009).

DNA extraction and sequencing

DNA was extracted from the MNY filter as described in Lau *et al.*, (2014). The DNA sample was sent to the Marine Biological Laboratory (MBL, Woods Hole, MA, USA) for whole-genome library prep using NuGen Ultralow Ovation system that included 18 cycles of PCR amplification of all adaptor-viable molecules (<http://nugen.com>). The metagenomic library (insert size ~ 160 bp) was then sequenced using an Illumina HiSeq 1000 system (Marine Biological Laboratory) for 101-bp paired-end reads. In total, 31 721 135 paired-end reads were generated. Sequences were then uploaded to the MG-RAST metagenomic pipeline (<http://metagenomics.anl.gov>) where they were merged and annotated according to Meyer *et al.* (2008). A total of 30 621 568 sequences passed the quality control of MG-RAST with an average sequence length of 158 ± 8 bp (MG-RAST metagenome ID: 4529964.3).

Metagenome assembly and annotation

The MG-RAST quality control-passed reads were directly assembled using IDBA-ud (Peng *et al.*, 2011) and only contigs longer than 200 bp were analyzed. Average coverage for each contig was calculated as the IDBA header designated read count multiplied by the average sequence length and divided by the length of the contig. Assembled contigs of length > 200 bp were used for gene prediction using Prodigal and the '-p meta' function (Hyatt *et al.*, 2012). Predicted open reading frames (ORFs) were

then clustered at 90% identity using CD-HIT-EST (Fu *et al.*, 2012). Annotations of the consensus ORFs were determined by using BLASTp against the m5nr database, collecting the top 10 hits with a maximum e-value threshold of 10^{-5} . A consensus protein annotation was then selected using a majority vote script, whereas taxonomy of the ORF was declared as the best hit to the selected annotation. The abundance of clustered ORFs was calculated by summing the average coverage of all contributing contigs to each ORF. A complete summary of assembly and annotation statistics is provided in Table 1. Notably, only annotations related to bacteria and archaea were included in this analysis.

Taxonomic diversity

The taxonomic diversity of the TT107 fracture water was determined from the relative abundances of single copy PEGs (SC-PEG) in the assembled data set as they have been shown to greatly reduce the biases, such as horizontal gene transfer or gene duplication, associated with assigning taxonomy from total protein diversity analyses (Ciccarelli *et al.*, 2006; Von Mering *et al.*, 2007). The set of SC-PEGs used in this study are reported in Supplementary Table S1.

Metagenomic comparisons

The unassembled TT107 metagenome was compared with 15 subsurface metagenomes publicly available on MG-RAST (Supplementary Table S2). Subsystem hierarchies for each metagenome were downloaded from MG-RAST with thresholds of 60% identity, alignment lengths > 25 and maximum e-value of 10^{-5} . Annotations were then filtered to only include PEGs classified under the RAST subsystem hierarchy 'carbon monoxide induced hydrogenase'. The MG-RAST reported abundances of these genes were then normalized (mean 0, variance 1) within each metagenome. The relative abundance of *Firmicutes* in each metagenome was calculated from all MG-RAST annotations (predicted proteins and ribosomal RNA genes).

Results and discussion

Geochemical characteristics

The water temperature during the 2-week sampling period ranged from 52.1°C to 50.4°C , the pH

Table 1 Assembly and annotation statistics

Raw reads	31 721 135 paired-end reads
Reads post QC	30 621 568 (avg. length 158 ± 8 bp)
Contigs	62 968
N50 of contigs	3258 bp
Longest contig	174 953 bp
Predicted ORFs	126 317
ORFs after 90% clustering	116 827
Percent of ORFs annotated	84.6%

Abbreviations: ORF, open reading frame; QC, quality control.

varied from 8.6 to 8.7, the Eh from -46 to -133 mV and the salinity remained constant at 0.20 ppt (Table 2). The $\delta^2\text{H}$ and $\delta^{18}\text{O}$ of the water lies very close to that reported for the Transvaal dolomite aquifer and the Global Meteoric Water Line (GMWL) (Lau *et al.*, 2014), but is displaced to more negative values compared with the annual mean of modern precipitation, suggesting a paleometeoric origin consistent with other mine waters investigated in this part of the Witwatersrand Basin. ^{14}C dating of the DIC indicates that the subsurface residence time of the fracture water is 1–6 kyr (Lau *et al.*, 2014). The electron donors identified in the fracture water included formate, acetate, H_2 , CO , HS^- , NH_4^+ , CH_4 , ethane, propane and butane (Table 2). Electron acceptors were limited and lower in concentration than the electron donors and consisted primarily of SO_4^{2-} , NO_3^- , HCO_3^- and O_2 (Table 2). The total dissolved nitrogen was entirely comprised of NH_4^+ and NO_3^- , whereas formate and acetate comprised 50% of the DOC (Table 2). Of the 47 redox reactions potentially constrained by these measurements, the FEF of 31 reactions were calculated (Supplementary Table S3). The 16 remaining FEFs were not calculated because of the fact that either the reactants were below detection or the ΔG was positive.

Energy conservation with the acetyl-CoA pathway

PEGs involved in six known carbon fixation pathways (Berg, 2011) were identified within the assembled metagenome (Figure 1) and the KEGG accessions of proteins used to identify the pathways are listed in Supplementary Table S4. Of these six carbon fixation pathways, the acetyl-CoA pathway was the most represented carbon fixation pathway in the metagenome (abundance = 1 273 022) despite containing the lowest number of representative genes searched for in the metagenome ($n=8$; Supplementary Table S4).

The dominance of the reductive acetyl-CoA pathway is, in part, because of the wide variety of organisms that have been reported to use this pathway. Such organisms include acetogens, methanogens, sulfate reducing bacteria (SRB), ammonia-oxidizing planctomycetes, an autotrophic archaeal SRB, *Archaeoglobales* (Berg, 2011), anaerobic facultative autotrophs (Schauder *et al.*, 1988) and, reversibly, with heterotrophs using carbon monoxide dehydrogenase (CODH) and acetyl-CoA synthase to oxidize acetyl-CoA (Rabus *et al.*, 2006). Callaghan *et al.* (2012) have also postulated that a reversed Wood-Ljungdahl pathway is carried out during the complete oxidation of alkanes under anaerobic conditions. The ΔG of many of the dominant anaerobic

^aBased upon cell counts using DAPI (Simkus *et al.*, 2015). ^bBased on the bacterial biomass calculated from 46 599 l of filter H_2O resulting in 41.2 μg of PLFA (0.9 pg/ml) (Simkus *et al.*, 2015).

Figure 1 Carbon cycle-specific genes. The six carbon fixation pathways (3-hydroxypropionate bicycle, Calvin cycle, dicarboxylate-hydroxybutyrate cycle, hydroxypropionate-hydroxybutyrate cycle, reductive acetyl-CoA cycle and reductive citric acid cycle) and other important C-cycling genes are listed on the x axis. The intensity of each block corresponds to the percent relative abundance (see legend) of each class (y axis) within a given individual gene/pathway (x axis). Gray squares indicate that no sequences were observed meeting the given criteria. At the top of each column is a bar chart that indicates the total abundance of each gene/pathway in the metagenome. The KEGG accessions for the genes used to annotate the six carbon fixation pathways are provided in Supplementary Table S4.

reactions hover close to the $\sim 70 \text{ kJ (mol)}^{-1}$ required for synthesis of ATP (Supplementary Table S3), suggesting that this fracture water system is energy limited. Therefore, in addition to the variety of

metabolisms the acetyl-CoA pathway has been reported to participate, the dominance of the acetyl-CoA pathway is, likely, due to the fact that it is the preferred carbon fixation pathway of bacteria and

archaea living close to the thermodynamic limit of life (Berg, 2011).

Of the PEGs identified in the acetyl-CoA pathway, 57.6% of the total calculated PEG abundance were related to the class *Clostridia* (Phylum: *Firmicutes*) and, despite having a low SC-PEG relative abundance (1%), *Deltaproteobacteria*-related acetyl-CoA pathway genes were enriched (18.8% of the eight indicative acetyl-CoA genes; Figure 1). At the individual PEG level, the majority of CODH and acetyl-CoA synthase PEGs, as well as formate dehydrogenase, an enzyme responsible for the oxidation of formate to CO₂ in the acetyl-CoA pathway, are related to known SRB in the classes *Clostridia* and *Deltaproteobacteria* (Figure 1). Organisms within these two taxa, including 'Ca. D. audaxviator', have been shown to exhibit both heterotrophic and autotrophic lifestyles, depending on the conditions (Londry *et al.*, 2004; Rabus *et al.*, 2006; Chivian *et al.*, 2008). The flexibility of individual microorganisms to perform both heterotrophy and autotrophy has been suggested to be a critical survival adaptation for hydrogeologically isolated systems as the carbon substrate concentrations may change over time (Moser *et al.*, 2005) and flexibility may also be an important feature of keystone species (for example, 'Ca. D. audaxviator') inhabiting the energy-limited TT107 fracture water.

Absence of aerobic heterotrophy

Six of the 10 most favorable reactions identified by FEF analysis required O₂ (Supplementary Table S3); however, *in situ* conditions were likely anoxic, despite the apparent detection of low amounts of dissolved O₂. Oxygen was measured soon after the borehole was opened for sampling (soon after it was drilled) and the Eh decreased (−46 to −133 mV) during the 13-day sampling period (Table 2). Therefore, the initial measurement of O₂ may reflect residual O₂ introduced during drilling of the borehole and may not be representative of *in situ* conditions. Metagenomic evidence also fails to

support the FEF-predicted aerobic activity. Particulate methane monooxygenase, soluble methane monooxygenase and alkane 1-monooxygenases PEGs were used as indicator PEGs for O₂-driven redox reactions. No PEGs related to particulate methane monooxygenase and soluble methane monooxygenase were identified in the metagenome and only two alkane 1-monooxygenases PEGs, related to those of an actinobacterium and a betaproteobacterium, were identified (Figure 1). Furthermore, the acetyl-CoA pathway, which contains genes that function only under strict anoxia (Berg, 2011), were found to be abundant in the metagenome (Figure 1). Therefore, the genetic potential for aerobic heterotrophic reactions is low when compared with anaerobic reactions. Consequently, only the FEF of anaerobic reactions are reported in Table 3.

Firmicutes-dominated community

Based on the analysis of SC-PEGs, Gram-positive *Firmicutes* were the most frequently detected phylum (57.4%) followed by *Euryarchaeota* (22.3%) and smaller contributions of *Proteobacteria* (8.7%), *Actinobacteria* (5.0%), *Crenarchaeota* (2.9%) and *Deinococcus-Thermus* (1.4%) (Figure 2). Before this study, the only other fully analyzed metagenome from the Witwatersrand Basin was from a filter sample of MP104 located 3 km SW of TT107 (Chivian *et al.*, 2008). Over 99% of MP104's reads were found to be related to a chemolithoautotrophic bacterium, 'Ca. D. audaxviator', capable of performing sulfate reduction and utilizing the reverse acetyl-CoA (Wood-Ljungdahl) pathway for CO₂ fixation. 'Ca. D. audaxviator' also comprised 98–100% of the 96 bacterial clones library (90% of the total prokaryotic community) of the Dr938H3 borehole (Moser *et al.*, 2005) located 1.7 km east of TT107. Although identified in the TT107 metagenome, 'Ca. D. audaxviator' accounts for only 1.6% of SC-PEG genera, whereas the most abundant genus in TT107 was its closest known relative within the family *Peptococcaceae*, *Desulfotomaculum* (8.9% of SC-PEGs).

Table 3 Ten anaerobic reactions with the greatest free energy flux

	ΔG (kJ mol ^{−1}) ^a	Free Energy Flux (kJ cell ^{−1} s ^{−1})

4H ₂ +2HCO ₃ [−] +H ⁺ → acetate+4H ₂ O	−10	−2.2 × 10 ^{−15}
Acetate+1.6NO ₃ [−] +0.6H ⁺ → 2HCO ₃ [−] +0.8H ₂ O+0.8N ₂	−181	−2.1 × 10 ^{−15}

^akJ mol^{−1} of 2e[−]. A table of the ΔG and free energy flux of 31 reactions can be found in Supplementary Table S3. ^bThe hydrolysis of butane represents an abiogenic reaction that is kinetically inhibited, but no known microorganisms has been isolated that performs this function.

Figure 2 Relative abundance of single copy protein encoding genes (SC-PEGs). The phylum (y axis) level abundances (x axis) of SC-PEGs are displayed. The percent relative abundance of each phylum is shown at the end of each bar. The following phyla are included in the 'Other' designation: *Korarchaeota*, *Acidobacteria*, *Chlamydiae*, *Fusobacteria*, *Fibrobacteres*, *Tenericutes* and *Cyanobacteria*.

In contrast to the unprecedented low alpha diversity of MP104 reported by Chivian *et al.* (2008), 289 genera were observed in the assembled metagenome of TT107 and, in a study by Magnabosco *et al.* (2014) using V6 16S rDNA amplicons, 549 plus genera were identified in six different South African boreholes that sampled fracture fluids at depths of 1–3.1 km. It is important to note that of the six boreholes (including a borehole from the 109 level of Tau Tona) sampled by Magnabosco *et al.* (2014), all samples displayed a similar community composition that was heavily dominated by *Proteobacteria* and contained <10% relative abundance of Firmicutes. This is consistent with other clone-based bacterial 16S rRNA gene surveys of other South African fracture water sites (Gihring *et al.*, 2006; Lin *et al.*, 2006a; Silver *et al.*, 2010) with the exception of two sites: Dr546bh1 (3.2 kmbls) (Moser *et al.*, 2003) and Ev818H6 (2.24 kmbls) (Davidson *et al.*, 2011). The 16S rRNA gene clone libraries for Dr546bh1 and Ev818H6 revealed *Firmicutes*-dominated communities but the numbers of clones were small, and thus, the full alpha

diversity may not have been sampled. The dominance of *Firmicutes*-related bacteria in TT107, Dr938H3 and MP104 suggests that the subsurface microbial community compositions of the South African fracture waters range from *Firmicutes*-dominated to *Proteobacteria*-dominated communities.

If we compare the $\delta^2\text{H}$ versus $\delta^{18}\text{O}$ of the fracture water for MP104, TT107, Dr938H3, Ev818H6, Dr546bh1 and the six sites sampled in the V6 amplicon study, we find that *Firmicutes*-dominated sites tend to be more removed from the GMWL than the six *Proteobacteria*-dominated V6 amplicon study sites, which sit on or near the GMWL (Figure 3). Location of fluids with respect to the GMWL is a key indicator of their origin and residence time in the subsurface. Fluids with relatively recent recharge from the surface (on a scale of tens of thousands of years) lie along the GMWL, reflecting their meteoric origin (Craig, 1961). In contrast, saline waters and brines that have been sequestered in the deep crystalline rocks of the Precambrian Shields worldwide have been shown to have $\delta^{18}\text{O}$ and $\delta^2\text{H}$ signatures well elevated over those of the GMWL

Figure 3 Community composition relative to geochemistry. Top: the $\delta^{18}\text{O}$ (‰) versus $\delta^2\text{H}$ (‰) of the six *Proteobacteria*-dominated sites included in Magnabosco *et al.* (2014) are shown in blue circles. *Firmicutes*-dominated sites (MP104, Dr938H3, Dr546bh1) are green squares and TT107 is shown as a red star. The black line indicates the GWML (Craig, 1961). Bottom: the $\delta^{18}\text{O}$ (‰) versus $\delta^2\text{H}$ (‰) versus Eh (mV) are shown using the same color scheme as (top). *The $\delta^{18}\text{O}$ and $\delta^2\text{H}$ for the *Firmicutes*-dominated Ev818H6 site were not measured but the geochemical similarity with other boreholes located on Ev818 suggests that the water is located far from the GWML (Davidson *et al.*, 2011). The Eh of Ev818H6 was measured to be -128 mV (Davidson *et al.*, 2011).

(Lippmann-Pipke *et al.*, 2011). The representation of the South African sites within the $\delta^2\text{H}/\delta^{18}\text{O}$ plot suggests that the fracture fluids in this study represent mixtures of ancient hydrothermal fluids and paleometeoric water (Onstott *et al.*, 2006; Lippmann-Pipke *et al.*, 2011). Furthermore, it appears that fracture fluids that have seen a smaller amount of mixing with paleometeoric waters, in combination with lower Eh (Figure 3), select for *Firmicutes* from mixed populations of *Proteobacteria* and *Firmicutes* residing in the paleometeoric water infiltrating the crustal fractures.

A similar pattern of community composition based on fluid origins has also been reported in the Fennoscandian Shield (Itävaara *et al.*, 2011), a terrestrial serpentinite system in northern California (the Cedars) (Suzuki *et al.*, 2013), the Tablelands Ophiolite (Brazelton *et al.*, 2013) and other serpentizing sites (Schrenk *et al.*, 2013). In the Fennoscandian Shield, the microbial communities inhabiting 100-m increments of the Outokumpu deep borehole (up to 1500 m depth) were reported. There, *Proteobacteria* dominated the oxygenated, shallow (0–900 m) samples, whereas *Firmicutes* dominated the deeper samples (900–1000 m, 1400–1500 m) of the borehole (Itävaara *et al.*, 2011). In the case of terrestrial serpentinites (Brazelton *et al.*, 2013; Schrenk *et al.*, 2013; Suzuki *et al.*, 2013), it has been reported that *Firmicutes* (and *Chloroflexi* in the case of Suzuki *et al.* (2013)) dominate serpentinite springs

fed solely by deep groundwater, whereas the sites whose water was a mixture of deep and shallow groundwater contain communities dominated by *Betaproteobacteria*. In the shallow sites, it is expected that the *Betaproteobacteria* such as *Hydrogenophaga* make use of the abundant O_2 and H_2 associated with the paleometeoric waters, whereas the *Firmicutes*-dominated sites are characterized by organisms capable of dealing with the low abundance of oxidants and/or with the ability to switch between autotrophic and mixotrophic growth (Schrenk *et al.*, 2013).

To explore whether or not the shift in the relative abundance of *Firmicutes* in subsurface microbial communities is associated with a change in metabolism, the abundance of PEGs related to the ‘carbon monoxide induced hydrogenase’ category were analyzed in parallel with taxonomic data from 16 unassembled subsurface metagenomes (See Materials and methods: Metagenomic Comparisons section). Notably, the ‘carbon monoxide induced hydrogenase’ category was selected because it is the category that is most directly related to the reductive acetyl-CoA pathway and, in turn, energy conservation (See Results and Discussion: Energy conservation with the acetyl-CoA pathway). From this analysis, we found that, in general, sites with a higher relative abundance of *Firmicutes* exhibited a higher abundance PEGs in this category (Figure 4). This trend further supports the hypothesis that organisms capable of using acetyl-CoA are selected for in energy-limited environments.

The recurring nature of the observation that distinct hydrogeological and geochemical niches select for *Proteobacteria*- versus *Firmicutes*-dominated communities in the South African subsurface, Fennoscandian Shield (Itävaara *et al.*, 2011), and terrestrial serpentinites (Brazelton *et al.*, 2013; Schrenk *et al.*, 2013; Suzuki *et al.*, 2013) suggests this may be a genuine feature of the subsurface biome and not an artifact of methodology. The observation raises the question of whether the geochemical and hydrogeological history of fracture fluids influences the nature of the *in situ* microbial community and how it develops. If such a correlation persists in future investigations, we may be able to predict a subsurface microbial community from geochemical measurements characterizing the subsurface environment. Such a tool would, in turn, improve our estimates of the distribution of microbes and our understanding of the controls on biodiversity in the terrestrial subsurface.

Biological carbon cycling at TT107

Methanogenesis. Aside from its distinctive bacterial community, TT107 also contains the highest relative abundance of *Euryarchaeota* (22%) yet reported in the South African subsurface (Gihring *et al.*, 2006; Simkus *et al.*, 2015). Methyl-coenzyme M reductase, the enzyme responsible for the final

Figure 4 The normalized abundances of PEGs within the ‘carbon monoxide induced hydrogenase’ RAST category are shown. For each PEG (bars), the normalized abundance of that PEG in a given subsurface metagenomes is shown (dots). The size and color of the dot represents the percent relative abundance of *Firmicutes* identified in the metagenome. The TT107 metagenome (this study) is represented by a large, black circle (45% relative abundance of *Firmicutes* in the unassembled metagenome).

step in methanogenesis, was identified primarily within the classes *Methanococci* and *Methanobacteria* representing 71.5% and 16.7% of methyl-coenzyme M reductase PEGs, respectively (Figure 1). Although the methanogens in TT107 are relatively more numerous than other sites within the Witwatersrand Basin, the FEF for biological CH_4 production ($-9.8 \times 10^{-15} \text{ kJ cell}^{-1} \text{ s}^{-1}$; Table 3) is less thermodynamically favorable than what has been reported for Dr938H3 (FEF as high as $1.0 \times 10^{-13} \text{ kJ cell}^{-1} \text{ s}^{-1}$) (Moser *et al.*, 2005) and Mponeng mine (FEF as high as $3.7 \times 10^{-14} \text{ kJ cell}^{-1} \text{ s}^{-1}$) (Lin *et al.*, 2006b). These differences reflect the higher H_2 concentrations found in Dr938H3 and MP104 relative to that of TT107. Previously, Sherwood Lollar *et al.* (2006) has interpreted the low H_2 concentration of South African fracture water as consistent with the depletion of H_2 by active methanogenesis. This interpretation is further supported by the combination of the $\Delta^{14}\text{C}_{\text{CH}_4}$ value ($-996 \pm 1\%$), $\Delta^{14}\text{C}_{\text{DIC}}$ value (-496.6%), the CH_4 concentration (8.8 mM) and the DIC concentration (570 μM), which yields an estimate the *in situ* CH_4 production rate by autotrophic methanogenesis of $8.7 \pm 2.3 \text{ nM CH}_4 \text{ yr}^{-1}$ at TT107 (Simkus *et al.*, 2015; Supplementary Table S5).

Anaerobic oxidation of hydrocarbons. This study determined that oxidation of short chain hydrocarbons via sulfate reduction is much more thermodynamically favorable than methanogenesis (Table 3). Notably, *Clostridia* and *Deltaproteobacteria*-related dissimilatory sulfite reductase PEGs for sulfate reduction were present in the metagenome (Figure 1) and could have an integral role to the coupling of sulfate reduction to propane (FEF = $-1.2 \times 10^{-13} \text{ kJ cell}^{-1} \text{ s}^{-1}$) and *n*-butane

(FEF = $-4.6 \times 10^{-14} \text{ kJ cell}^{-1} \text{ s}^{-1}$) oxidation. Currently, little is known about the enzymes that catalyze anaerobic alkane oxidation and, to date, only two genomes, *Desulfococcus oleovorans* Hxd3 and *Desulfatibacillum alkenivorans* AK-01 (both *Deltaproteobacteria*), are available among anaerobic alkane oxidizers. Of these two organisms, only the mechanism of alkane activation for *D. alkenivorans* AK-01 is known (Callaghan *et al.*, 2012). The activation of alkanes by *D. alkenivorans* AK-01 is catalyzed by an alkylsuccinate synthase that was also identified in the TT107 metagenome (Figure 1; Callaghan *et al.*, 2008). As the complete oxidation of alkanes by *D. alkenivorans* AK-01 is believed to proceed by reversing the Wood-Ljungdahl (reductive acetyl-CoA) pathway, it is possible that anaerobic alkane oxidizers contribute to the elevated abundance of *Deltaproteobacteria*-related acetyl-CoA pathway genes described earlier.

Carboxydutrophy. CO oxidation coupled to the reduction of H_2O to H_2 was the second most powerful anaerobic reaction (Table 3; FEF = $-1.1 \times 10^{-13} \text{ kJ cell}^{-1} \text{ s}^{-1}$) and provides another role for the numerous CODH PEGs. A carboxydovore-related CODH with 94% nucleotide identity to *Desulfotomaculum carboxydivorans* CO-1-SRB was identified in the TT107 metagenome (Supplementary Table S6). *D. carboxydivorans* CO-1-SRB is a bacterium that was cultured in 100% pCO headspace and with the absence of any other electron donors, carbon substrates and sulfate (Parshina *et al.*, 2005). Parshina *et al.* (2005) found that the *D. carboxydivorans* CO-1-SRB oxidized CO to CO_2 while reducing H_2O to H_2 and, upon the addition of sulfate, switched to sulfate reduction. In TT107, *Desulfotomaculum*, is the most

abundant annotated genus (relative abundance = 8.9%) and, because of the fact that the oxidation of CO is the second most favorable anaerobic reaction in TT107 (Table 3), it is conceivable that, in addition to the fixation of CO₂ via the acetyl-CoA pathway, the utilization of CO by carboxydivores is an important catabolic process in the TT107 fracture.

Acetogenesis. Acetogens are famous for their ability conserve energy (Müller, 2003) and *Clostridia*-related acetate kinase PEGs that may be representative of acetogenesis were identified (Figure 1). However, given that the ΔG for the acetogenic reaction is only $-10 \text{ kJ (mol } 2e^-)^{-1}$ and the FEF is only $2.2 \times 10^{-15} \text{ kJ cell}^{-1} \text{ s}^{-1}$ (two orders of magnitude lower than top two FEF values of Table 3), the acetate kinase PEGs, most likely, perform the function of phosphorylating acetate for biosynthesis rather than contributing biogenic acetate to the DOC pool.

Summary. The observation that the FEFs of hydrocarbon oxidation reactions coupled to sulfate reduction are far greater than those of methane- and acetate-generating processes suggests that the TT107 fracture water was likely dominated by mixotrophs or heterotrophs that utilize the oxidative acetyl-CoA pathway. The presence of alkylsuccinate synthase genes related to the anaerobic alkane oxidizer *D. alkenivorans* AK-01 and a carboxydovore-related CODH/acetyl-CoA synthase gene cluster provide a molecular explanation for how the highly favorable anaerobic hydrocarbon and CO oxidation reactions may proceed in TT107.

Further supporting these mixed modes of carbon metabolisms are the recently reported carbon isotope signatures of PLFA collected from TT107 ($\delta^{13}\text{C}_{\text{PLFA}} = -11$ to -25.5‰ ; $\Delta^{14}\text{C}_{\text{PLFA}} = -633.2 \pm 11.3\text{‰}$) (Simkus *et al.*, 2015). When these values are compared with the carbon isotope values for DIC and CH₄ (Simkus *et al.*, 2015), we find that the $\Delta^{13}\text{C}_{\text{DIC-PLFA}}$ is 6.0‰ to 20.5‰, which is consistent with the preferential uptake of the lighter isotope of carbon from DIC by autotrophic microbial communities (Boschker and Middelburg, 2002). The $\Delta^{14}\text{C}$ of TT107's PLFA ($\Delta^{14}\text{C}_{\text{PLFA}} = -633.2 \pm 11.3\text{‰}$) (Simkus *et al.*, 2015) is, however, lower than the $\Delta^{14}\text{C}$ of the DIC ($-496.6 \pm 2.1\text{‰}$) (Lau *et al.*, 2014) resulting in a $\Delta^{14}\text{C}_{\text{DIC-PLFA}} = 143\text{‰}$. This $\Delta^{14}\text{C}_{\text{DIC-PLFA}}$ indicates microbial consumption of carbon source(s) in addition to DIC, which are likely the abiogenic hydrocarbons. The use of the acetyl-CoA pathway as both an oxidative and reductive pathway is a likely explanation for the $\Delta^{13}\text{C}_{\text{DIC-PLFA}}$ and $\Delta^{14}\text{C}_{\text{DIC-PLFA}}$ patterns.

Conclusions

The combination of steady-state FEF calculations and metagenome analyses suggest that the TT107 fracture water is home to both organic and inorganic

C utilizers. *Firmicutes* dominate the TT107 fracture water and distinguish it from *Proteobacteria*-dominated communities found in waters with younger residence times and higher Eh in the South African subsurface. The selection for *Firmicutes* has also been observed in other terrestrial subsurface sites and may be driven by the energy limitations that come with a lowered Eh of the fracture water. These results support the growing evidence that the deep subsurface biosphere is a more dynamic ecosystem than previously understood and that the bacterial and archaeal inhabitants have the capability to actively contribute and respond to the transformation of carbon within the deep subsurface.

Data availability

The FASTQ reads of the TT107 metagenome are available on MG-RAST (metagenome ID: 4529964.3) and can be accessed via <http://metagenomics.anl.gov/linkin.cgi?metagenome=4529964.3>.

Conflict of Interest

The authors declare no conflict of interest.

Acknowledgements

We thank G Slater and D Simkus for insightful discussions on carbon isotope signatures. In addition, we would like to thank F Vermeulen, M Pienaar, A Munro, and the other staff from Tau Tona gold mine (AngloGold Ashanti Ltd) for providing access and assistance during sampling, T Tlalajoe and M Maleke for their assistance in sampling and field measurements, and the Marine Biological Laboratory for performing library prep and metagenomic sequencing. Subsurface research was funded by the National Geographic Society, National Science Foundation (NSF) and Natural Sciences and Engineering Research Council of Canada (NSERC) to BSL. NSF funding was provided to TLK (EAR-0948335), TCO (EAR-0948659), and CM (DGE-1148900). Any opinion, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the National Science Foundation. CM also received funding from the Center for Dark Energy Biosphere Investigations Graduate Fellowship and this article is C-DEBI Contribution 276.
