Enhanced nonlinear interactions in quantum optomechanics via mechanical amplification

Marc-Antoine Lemonde¹, Nicolas Didier^{1,2} & Aashish A. Clerk¹

The quantum nonlinear regime of optomechanics is reached when nonlinear effects of the radiation pressure interaction are observed at the single-photon level. This requires couplings larger than the mechanical frequency and cavity-damping rate, and is difficult to achieve experimentally. Here we show how to exponentially enhance the single-photon optomechanical coupling strength using only additional linear resources. Our method is based on using a large-amplitude, strongly detuned mechanical parametric drive to amplify mechanical zero-point fluctuations and hence enhance the radiation pressure interaction. It has the further benefit of allowing time-dependent control, enabling pulsed schemes. For a two-cavity optomechanical set-up, we show that our scheme generates photon blockade for experimentally accessible parameters, and even makes the production of photonic states with negative Wigner functions possible. We discuss how our method is an example of a more general strategy for enhancing boson-mediated two-particle interactions and nonlinearities.

The field of quantum cavity optomechanics aims at synthesizing quantum states of light and motion using radiation pressure, the fundamental nonlinear interaction between photons and phonons. Considerable effort is currently devoted to reaching the true quantum regime, where nonlinear signatures are observed at the single-photon level^{1,2}. In the canonical system of a cavity comprising a movable mirror, the quantum nonlinear regime requires the single-photon coupling constant g to be comparable to both the mechanical resonator frequency ω_M , as well as the cavity-damping rate κ (refs 3–6). Current experiments are still far from this regime.

The simplest strategy to enhance the optomechanical interaction is to coherently drive the cavity. This approach has facilitated a wide variety of interesting phenomena, ranging from ground-state cooling of the mechanical resonator^{7,8} to mechanically mediated state transfer⁹, and the generation of squeezed light^{10–12}. The optomechanical interaction is however effectively linearized in this strong driving regime, and hence there is generally no enhancement of quantum nonlinear effects. For enhanced nonlinearity, one can tune the strong drive so that the weak residual optomechanical nonlinearity becomes resonant^{13,14}. The quantum regime is then reached for $g \sim \kappa$, where the damping rate of the cavity κ can be much smaller than ω_M . A similar enhancement of quantum nonlinear effects is found in undriven two-cavity set-ups¹⁵, where the energy difference between the optical modes is set to render the nonlinear optomechanical interaction resonant¹⁶ or nearly resonant^{17,18}. Enhancement of the nonlinearity has also been proposed in a transient scheme¹⁹ and in optomechanical arrays²⁰. Experimentally, these approaches are still not sufficient: for systems in the optimal good cavity regime ($\omega_M > \kappa$), the largest achieved couplings g are at most a percent of κ (refs 1,2,21).

In this paper, we present a new method for enhancing the single-photon optomechanical interaction for systems deep in the well-resolved sideband regime. It enables true quantum nonlinearity even when the single-photon coupling g is much smaller than the cavity-damping rate κ . Crucially, our scheme results in a tunable nonlinearity, and only requires additional linear resources: it does not require a coupling to an auxiliary quantum nonlinear system (like a qubit^{22–24}). The key idea is to use detuned parametric driving of the mechanics to increase the effective scale of mechanical zero-point position fluctuations x_{ZPF} . This amplification directly enhances the coupling strength (as $g \propto x_{\text{ZPF}}$), while the large detuning allows the mechanics to still effectively mediate a photon–photon interaction. So far, parametric mechanical driving has been studied only in the linearized regime of optomechanics^{25–27}.

Combined with the resonant enhancement possible in two-cavity set-ups^{16–18}, our novel approach lets one reach the quantum regime in current state-of-the-art experiments ($g \sim 10^{-2}\kappa$). In addition, by controlling the parametric-drive amplitude, the nonlinear interaction can be rapidly turned on and off in time, greatly extending its utility. We stress that due to the fundamental asymmetry between photons and phonons in the optomechanical interaction, parametrically driving the cavity²⁸ does not enhance single-photon quantum effects. While such photonic parametric driving generates an enhanced nonlinearity, this nonlinearity necessarily involves states with large photon numbers (that is, squeezed Fock states), reducing its utility (Supplementary Fig. 1). As we discuss in detail, parametrically driving the mechanics results in very different physics and a true enhancement of single-photon nonlinearity.

The approach outlined in our work is a particular example of a general strategy for enhancing two-particle interactions using only linear resources. It could thus have applications to continuous variable quantum information processing, where

strong nonlinearities are crucial for universal control, but often difficult to achieve²⁹. In our optomechanical system, the mechanical resonator mediates an effective retarded interaction between photons^{3,4,17,30}. Our scheme enhances this interaction by using a parametric drive to manipulate the mechanical dynamics. Similar improvements can be obtained in any system where bosonic modes mediate a two-particle interaction: by parametrically driving the intermediate modes, interactions can be greatly enhanced (see, for example, phonon-mediated electron–electron interactions in superconductivity^{31–33}). An intuitive picture of the physics is provided by the effective Keldysh action describing the cavity photons in our system. This approach explicitly connects the nonlinear interaction to the mechanical Green’s functions, and shows how a large detuning of the parametric drive is important to get a time-local interaction.

Results

System. We consider an optomechanical (OM) system consisting of two optical modes coupled to a single mechanical resonator (MR) via radiation pressure (cf. Fig. 1), where the interaction is of the form $g(\hat{a}_2^\dagger \hat{a}_1 + \hat{a}_1^\dagger \hat{a}_2)(\hat{b} + \hat{b}^\dagger)$. Here $\hat{a}_{1,2}$ and $\hat{b}$ are the annihilation operators of the optical modes 1, 2 and the MR, respectively. Such three-mode OM systems have been discussed extensively in the literature^{16–18} and have been realized experimentally^{34–36}. As already discussed, if one tunes the mode splitting $\omega_{21} \equiv \omega_2 - \omega_1$ to make the optomechanical interaction resonant, quantum nonlinear effects can be observed when the OM coupling g is comparable to the damping rate κ of the cavities^{16–18}.

We wish to enhance this generic system so that single-photon quantum effects are possible even when $g \ll \kappa$. To that end, we introduce a strongly detuned parametric drive to the mechanics. The generic system Hamiltonian then reads

$$\hat{H} = \Delta \hat{b}^\dagger \hat{b} - \frac{1}{2} (\lambda \hat{b}^2 + \lambda^* \hat{b}^{\dagger 2}) + g [\hat{a}_2^\dagger \hat{a}_1 \hat{b} e^{-i\delta t} + \text{H.c.}] \quad (1)$$

Here we work in an interaction picture with respect to the free cavity Hamiltonians and, for the mechanics, with respect to the pump frequency ω_p . The parameter λ is the parametric-drive strength, $\Delta \equiv \omega_M - \omega_p$ and $\delta = \omega_p - \omega_{21}$. We have assumed $\omega_p + \omega_{21}$ large enough to neglect highly non-resonant interaction terms; this approximation is always valid for the parameters considered in this work (Supplementary Note 2). In what follows, we always stay in the regime where the MR is stable even without dissipation, that is, $\lambda < \Delta$. The quadratic part of $\hat{H}$ is then diagonal when expressed in terms of the Bogoliubov mode $\hat{\beta}$, defined as $\hat{\beta} = \hat{b} \cosh r - \hat{b}^\dagger \sinh r$, with energy $E_\beta = \Delta / \cosh 2r$. The

Figure 1 | Sketch of the system. Tunnelling between two optical cavities (blue circles) is mediated by a mechanical mode (red ellipse) on which a large-amplitude, strongly detuned parametric drive is applied to amplify its $\hat{X}$ quadrature. This scheme results in an exponential enhancement of the single-photon coupling constant g , thereby amplifying the resulting effective photon–photon interaction.

parameter r is set by the parametric-drive strength, $\tanh 2r = \lambda/\Delta$. Experimentally, detuned parametric drives have already been employed in optomechanics set-ups^{37,38}, and are particularly compatible with recent state-of-the-art electromechanical set-ups³⁹. Large amounts of mechanical parametric amplification has also recently been obtained in optomechanics (> 30 dB), albeit in a non-stationary regime⁴⁰. In general, the maximum value of Δ will be constrained by ω_M and the desired amount of amplification, though the form of this constraint depends on the particular implementation of the mechanical parametric drive (for example, spring constant modulation or the auxiliary cavity method, Supplementary Note 3).

Enhanced, tunable nonlinear interactions. The detuning δ can be chosen to select the nature of the nonlinear interaction that is effectively amplified. Taking $\delta = 0$ gives rise to the interaction

$$\hat{H}_{\text{SRP}} = E_\beta \hat{\beta}^\dagger \hat{\beta} + \tilde{g} (\hat{a}_2^\dagger \hat{a}_1 + \hat{a}_1^\dagger \hat{a}_2) (\hat{\beta} + \hat{\beta}^\dagger) + \hat{H}'_{\text{SRP}} \quad (2)$$

For large amplification (that is, for $e^{2r} \gg 1$) and a state where the Bogoliubov mode is not strongly squeezed, the term $\hat{H}'_{\text{SRP}} = \frac{1}{2} g e^{-r} (\hat{\beta} - \hat{\beta}^\dagger) (\hat{a}_2^\dagger \hat{a}_1 - \hat{a}_1^\dagger \hat{a}_2)$ can be dropped and $\hat{H}_{\text{SRP}}$ becomes similar to the standard radiation pressure interaction in the two-cavity OM system^{16–18}. While the effects of $\hat{H}'_{\text{SRP}}$ are negligible for the parameters considered in this work, we keep their contributions in all subsequent numerical results. We now however have an exponentially enhanced effective single-photon coupling constant

$$\tilde{g} = \frac{1}{2} g e^r \gg g \quad (3)$$

This enhancement is a direct consequence of the parametric drive: it amplifies the vacuum fluctuations of the mechanical $\hat{X} \equiv \hat{b} + \hat{b}^\dagger$ quadrature, and thus enhances the coupling of the cavities to this quadrature. The effective photon–photon interaction induced by equation (2) is further enhanced compared with a standard single-cavity OM set-up, as the Bogoliubov mode energy E_β is also tunable and can be made much smaller than ω_M . However, one also needs this mechanically mediated interaction to be sufficiently time-local; as shown below, this further constrains $E_\beta > \tilde{g}, \kappa$. The induced photon–photon interaction thus scales as $\tilde{g}^2/E_\beta$, as opposed to $\sim g^2/\omega_M$ in a standard OM cavity^{3,4}. We stress that only the amplification effect of the parametric drive is crucial here. This means that the mechanics does not have to be in a vacuum-squeezed state (that is, the Bogoliubov mode can have a thermal population).

If one instead tunes frequencies so that $\delta \approx E_\beta > \tilde{g}, \kappa$, one can make an additional rotating wave approximation, yielding the interaction ($e^{2r} \gg 1$)

$$\hat{H}_{\text{PAT}} = (E_\beta - \delta) \hat{\beta}^\dagger \hat{\beta} + \tilde{g} (\hat{a}_2^\dagger \hat{a}_1 \hat{\beta} + \hat{a}_1^\dagger \hat{a}_2 \hat{\beta}^\dagger) \quad (4)$$

This is a phonon-assisted photon-tunnelling interaction, with an enhanced interaction strength $\tilde{g}$ again given by equation (3). This form of interaction (without any parametric enhancement) has been studied in the resonant regime ($E_\beta = \delta$)¹⁶, as well as in the detuned regime ($\tilde{g}, \kappa < |E_\beta - \delta| \ll |E_\beta + \delta|$)¹⁷. While tuning the parametric-drive frequency lets us pick the form of the effective nonlinear interaction, tuning its amplitude lets us control the interaction strength. As discussed below, the possibility to modulate the interaction strength in time is extremely useful to prepare the β mode in the desired state while preventing mechanical heating.

We stress that our scheme allows in principle arbitrarily large nonlinearity enhancements in optomechanics using only additional linear resources (that is, a large parametric drive that is strongly detuned). In practice, the achievable enhancement will be limited by the maximum detuning Δ possible (needed to ensure $E_\beta > \tilde{g}, \kappa$) and by the stability of the parametric drive (one should not cross the instability threshold). Thus, if one wants to use large r values to enhance the interaction, the requirement that $E_\beta > \kappa, \tilde{g}$ implies that the system must be deep in the well-resolved sideband regime. The requirements on the parametric drive and the achievable amplification r are summarized in Table 1. For a standard realization of mechanical parametric driving via the modulation of the spring constant, Δ is further constrained by ω_M and the amount of amplification. A much weaker constraint applies if the parametric drive is realized using an auxiliary cavity (Supplementary Note 3). Despite these caveats, our approach represents a practically attractive route towards single-photon strong coupling, given the difficulty of engineering systems with an intrinsically large value of g .

Dissipation and mechanical state preparation. In addition to the coherent dynamics described by equation (1), we take into account the coupling of the MR and both optical modes to Markovian baths; these cause the cavities to be damped at a rate κ , and the mechanics at a rate γ . In the presence of a parametric drive, the noise coming from the MR bath is also amplified. In the weak mechanical dissipation limit ($\gamma \ll E_\beta$), a MR bath of thermal occupancy $\bar{n}_M^{\text{th}}$ corresponds to a bath for the β mode of effective temperature $\bar{n}_\beta^{\text{th}} = \bar{n}_M^{\text{th}} \cosh 2r + \sinh^2 r$. For mechanical excitations off-resonant with the optical modes, that is, $E_\beta - \delta > \kappa, \tilde{g}$ and $e^{2r} \gg 1$, the cavities are heated through the OM interaction at a rate $\Gamma \propto \gamma [\tilde{g} e^r / (E_\beta - \delta)]^2 (2\bar{n}_M^{\text{th}} + 1)$ (Supplementary Note 4); left unchecked, this heating could corrupt any nonclassical behaviour induced by the enhanced single-photon OM interaction. To circumvent amplified noise from the mechanical bath, a possible strategy is to add an optical mode to the system, and use it to keep the Bogoliubov mode in its ground state via dissipative squeezing^{41–47}. This steady-state technique has recently been implemented experimentally^{48–50}.

Table 1 | Parameter regime needed to get important amplification of the single-photon coupling constant $\tilde{g} = ge^r/2$ using a parametric drive on the mechanical resonator.

Necessary parameter regime
Good cavity limit
Large parametric-drive detuning
Strong parametric drive

$$\begin{aligned} \kappa &\ll \omega_M \\ \kappa &\ll \Delta \\ \lambda &\rightarrow \Delta \end{aligned}$$

Optimal enhanced interaction

Requirement for local-in-time interaction

$$\begin{aligned} \tilde{g}_{\text{opt}} &\approx (g/2)^{2/3} \Delta^{1/3} \\ \tilde{g}_{\text{opt}} &\approx g \sqrt{\Delta/2\kappa} \end{aligned}$$

$$\begin{aligned} (g/2)^2 \Delta &> \kappa^3 \\ (g/2)^2 \Delta &< \kappa^3 \end{aligned}$$

The enhanced single-photon coupling that leads to maximal photon blockade, which corresponds to having an effectively local-in-time photon–photon interaction, is denoted as $\tilde{g}_{\text{opt}}$.

As an alternative to using an additional optical mode, one can instead take advantage of the tunability of the parametric drive. Indeed, one can first turn on the parametric drive on a timescale τ_{on} short enough to avoid significant perturbation of the initial photon state, $\tau_{\text{on}} < 1/\kappa, 1/\tilde{g}$. Then, one can let the system interact for a time τ sufficient to observe nonclassical signatures, $\tau > 1/\tilde{g}$. This protocol has to be performed in a total time short enough to avoid unwanted cavity heating, $\tau_{\text{on}} + \tau < 1/\Gamma$. This is possible given that Γ remains $\ll \tilde{g}$ even for large enhancement factors $e^{2r} \gg 1$, as the intrinsic mechanical damping γ is extremely low in state-of-the-art experiments.

In such pulsed schemes, it is crucial that the initial ramp of the parametric-drive amplitude prepares the β mode reasonably close to its ground state; this is needed to obtain the radiation pressure interaction in equation (2) (i.e. the effects of $\hat{H}_{\text{SRP}}'$ remain negligible). If the mechanics $\hat{b}$ remains in its ground state, as it would occur for an abrupt turn on of the parametric drive, then the β mode is in a highly squeezed state and this squeezing completely negates the exponential enhancement of the interaction in equation (2). While an adiabatic protocol would prevent β -mode squeezing, it would be too slow to prevent important perturbation of initial cavity states. Indeed, for $E_\beta \sim \kappa, \tilde{g}$, adiabaticity is ensured for turn-on times much longer than $1/E_\beta \sim 1/\kappa, 1/\tilde{g}$. An appropriate solution is to use the so-called ‘counterdiabatic’ or ‘transitionless’ driving (TD) protocols^{51–53}. These require one to control the amplitude and the phase of the parametric drive, $\lambda(t) = \lambda_0(t) + i\lambda_1(t)$ (cf. Fig. 2a). The term $\lambda_0(t)$ defines the instantaneous Bogoliubov mode of interest through $\tanh 2r(t) = \lambda_0(t)/\Delta$, with $\lambda(0) = 0$ and $\lambda(\tau_{\text{on}}) = \lambda$. The correction $\lambda_1(t) = -\dot{r}(t)$ ensures that the MR stays in the ground state of the instantaneous Bogoliubov mode despite non-adiabatic effects. In Fig. 2b, we show the evolution of the β mode without nonlinear interaction ($g = 0$) and for a MR initially in its ground state. Using TD, the final β mode is prepared in its ground state for

$\tau_{\text{on}} \ll 1/\kappa$. Such an ideal preparation is not possible if one just suddenly turns on $\lambda(t)$.

Standard radiation pressure interaction. We focus in the remainder of the paper on the case where the relative detuning $\delta = 0$, such that the OM interaction is described by $\hat{H}_{\text{SRP}}$, equation (2); we further take parameters such that $E_\beta > \kappa, \tilde{g}$ to ensure a sufficiently wide-bandwidth mechanically mediated photon–photon interaction. This two-photon interaction can be understood as an effective ‘feedback’ process: the photonic system first displaces the MR and then this displacement results in an effective forcing of the photonic system^{3,4,17,30}. The conventional approach to describing such an interaction uses a polaron transformation $\hat{U} = \exp\{(\tilde{g}/E_\beta)(\hat{a}_s^\dagger \hat{a}_1 + \hat{a}_1^\dagger \hat{a}_2)(\hat{\beta}^\dagger - \hat{\beta})\}$ on $\hat{H}_{\text{SRP}}$, leading to the polaron Hamiltonian $\hat{H}_{\text{SRP}}^{\text{pol}} = \hat{U} \hat{H}_{\text{SRP}} \hat{U}^\dagger$

$$\hat{H}_{\text{SRP}}^{\text{pol}} = E_\beta \hat{\beta}^\dagger \hat{\beta} - \Lambda (\hat{a}_2^\dagger \hat{a}_1 + \hat{a}_1^\dagger \hat{a}_2)^2 \quad (5)$$

$$= E_\beta \hat{\beta}^\dagger \hat{\beta} - \Lambda (\hat{a}_s^\dagger \hat{a}_s - \hat{a}_a^\dagger \hat{a}_a)^2 \quad (6)$$

with $\Lambda = \tilde{g}^2/E_\beta$. Equation (6) is written in the symmetric/antisymmetric photonic basis, defined by the modes $\hat{a}_{s,a} = (\hat{a}_1 \pm \hat{a}_2)/\sqrt{2}$. When only one of the photonic modes is driven (symmetric or antisymmetric)³⁶, the nonlinearity is a Kerr interaction and the physics of the radiation pressure interaction in a single-cavity OM system is recovered. As described in refs 3,4, the polaron transformation only diagonalizes the Hamiltonian of the closed system. When including dissipation or a drive, the finite displacement of the β mode caused by the photons has to be accounted for ($\langle \hat{\beta} \rangle = \tilde{g}/E_\beta \langle \hat{a}_s^\dagger \hat{a}_s - \hat{a}_a^\dagger \hat{a}_a \rangle$). As a result, when a photon enters or leaves a cavity, it generates phonon sideband excitations (that is, excitations of the β mode); this is analogous to standard Franck Condon physics.

Photon blockade. The photon–photon interaction in equation (6) can lead to photon blockade, a quantum phenomenon characterized by a strong suppression of the probability of having more than one photon in the cavity together with antibunched photon statistics. It has been thoroughly studied in the single-cavity set-up³; here we highlight the advantage of parametrically driving the MR. Photon blockade is typically quantified by the equal-time intensity correlation function $g_a^{(2)}(0) = \langle \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} \rangle / \langle \hat{a}^\dagger \hat{a} \rangle^2$ that drops below the classical bound, $g_a^{(2)}(0) < 1$. Note that, although $g_a^{(2)}(0) < 1$ can be obtained with Gaussian states obeying a linear dynamics⁵⁴, here the $g_a^{(2)}(0)$ suppression cannot be reproduced if the interaction $\hat{H}_{\text{SRP}}$ is linearized (Supplementary Fig. 2).

The intensity correlation of the symmetric mode, $g_a^{(2)}(0)$, is calculated in presence of a weak probe drive on $\hat{a}_s$. We use a standard quantum master equation to describe the coherent dynamics governed by $\hat{H}_{\text{SRP}}$ and the dissipation to zero-temperature baths of the β and $\hat{a}_{1,2}$ modes. We thus assume that the MR is either cooled using dissipative squeezing, or has been prepared in its ground state via the TD protocol. The resulting $g_a^{(2)}(0)$, with and without mechanical parametric drive, are compared in Fig. 3a. The parametric drive markedly reduces $g_a^{(2)}(0)$, especially in the experimentally accessible regime $g < 0.1\kappa$, for example, for $g = 0.1\kappa$, $g_a^{(2)}(0) \approx 0.8$ ($g_a^{(2)}(0) \approx 0.3$) for 20 dB (30 dB) of amplification while $g_a^{(2)}(0) \approx 0.999$ without parametric drive. In the limit $\tilde{g} > \kappa$, $g_a^{(2)}(0)$ is minimized for $E_\beta = 2\tilde{g}$, that is, for a parametric detuning $\Delta = \frac{1}{2}\tilde{g}e^{3r}$ (cf. insets of Fig. 3). For 20 dB of amplification and $g \sim 0.1\kappa$, this implies $\Delta \sim 100\kappa$. The optimal E_β corresponds to the situation where, in the polaron

Figure 2 | Initialization of the mechanical state. Fast turn on of mechanical parametric driving using the TD scheme (see main text). **(a)** Time dependence of the parametric driving strength $\lambda(t) = \lambda_0(t) + i\lambda_1(t)$, corresponding to a Gaussian profile for the instantaneous amplification factor $r(t)$ [$\tanh 2r(t) = \lambda_0(t)/\Delta$]. The final value of $\lambda(t)$ corresponds to $e^{2r} = 20$ dB. The pulse is chosen to ramp up the parametric drive in a time much shorter than the inverse Bogoliubov-mode energy E_β . **(b)** Evolution of the mechanical state, as characterized by the population of the Bogoliubov mode $\hat{\beta}$. The solid red line is for the TD approach, showing preparation of a pure squeezed state (characterized by no β -mode excitations) in a time $\sim 0.1/E_\beta$. In contrast, a sudden (step-function) turn on of the parametric drive results in β mode being far from its ground state (red dashed line). The TD protocol plays a crucial role in our scheme, as it allows a rapid turn on of the mechanically mediated photon–photon interaction, without any spurious effects resulting from a large initial β -mode population. Neither a purely adiabatic protocol nor a sudden diabatic approach would be sufficient. Here the mechanical dissipation is $\gamma = 10^{-4}E_\beta$ and $g = 0$, but the results are unchanged for $g \neq 0$ and a sufficiently small γ .

Figure 3 | Nonclassical photon intensity correlations. Intensity correlation function $g_{as}^{(2)}(0) = \langle \hat{a}_s^\dagger \hat{a}_s^\dagger \hat{a}_s \hat{a}_s \rangle / \langle \hat{a}_s^\dagger \hat{a}_s \rangle^2$, for a mechanical parametric drive yielding the optomechanical interaction $\hat{H}_{\text{SRP}}$ (cf. equation (2)), and for a weak coherent probe tone applied to the cavities. In **a**, $g_{as}^{(2)}(0)$ is plotted as a function of g for different values of the amplification factor e^{2r} ; in **b** it is plotted as a function of e^{2r} for a fixed value of g . For each value of g and r , the probe frequency and the parametric-drive detuning Δ are optimized to minimize $g_{as}^{(2)}(0)$ (Δ is plotted in insets). The amplitude of the weak probe is kept fixed. **(a)** The violation of the classical bound $g_{as}^{(2)}(0) \geq 1$ is enhanced in our scheme: the presence of the mechanical parametric drive leads to significant suppression of $g_{as}^{(2)}(0)$ for experimentally accessible couplings $g \sim 0.01\kappa$. **(b)** Mechanical parametric driving brings the optical field deep into the nonclassical region even for $g = 0.05\kappa$, leading to non-Gaussian optical fields (Supplementary Fig. 2). For these results, dissipative squeezing is used, with a damping rate $\gamma_\beta = 0.001\kappa$.

picture (cf. equation (6)), the state with two symmetric photons ($|2, 0, 0\rangle$) and the corresponding first phonon sideband ($|2, 0, 1\rangle = \beta^\dagger |2, 0, 0\rangle$) are equally detuned from the one-photon state ($|1, 0, 0\rangle$). The intensity correlations are described to a good approximation by $g_{as}^{(2)}(0) \approx 1/[1 + 0.8(\tilde{g}/\kappa)^2]$. Increasing the parametric drive is thus, in principle, always beneficial since, for any coupling $g < \kappa$, there is always an amplification strength r that leads to a desired $g_{as}^{(2)}(0) < 1$. For instance, $g_{as}^{(2)}(0) = 0.5$ is obtained for $e^r \approx 2.2\kappa/g$.

Negative Wigner functions. The possibility for time-dependent control of the photon–photon interaction in our system opens the

door to a wealth of interesting functionalities. Perhaps the most demanding challenge is the production of photon states exhibiting strongly negative Wigner functions. We show here how this can be accomplished in our set-up, in a manner that produces negativity both in the states of intracavity and propagating photons. Crucially, this can be done using a bare coupling g that is still smaller than the cavity-damping rate ($g/\kappa \sim 0.3$). We stress that this kind of negative Wigner function generation would be essentially impossible without mechanical parametric driving: not only would one require a g that is at least an order of magnitude larger, one would need some alternate means for controlling it in time. Our scheme thus significantly lowers the level of experimental improvement needed for generating negative photonic Wigner functions.

One first prepares cavity 1 in a low-amplitude coherent state using a classical laser drive while cavity 2 remains in vacuum (Fig. 4a). The mechanical parametric drive is off during this step, so that there is essentially no photonic nonlinearity. Once this initial cavity state is prepared, the cavity drive is turned off, and the photonic interaction is amplified by ramping up the mechanical parametric drive. The TD scheme described earlier allows this turn-on step to be completed in a time $\tau_{\text{on}} \ll 1/\kappa, 1/\tilde{g}$, that is, fast enough to be effectively instantaneous to the photons. At the same time, this scheme ensures that the β mode is prepared in its ground state.

We pick a frequency detuning of the parametric drive $\delta = 0$ to realize the two-photon tunnelling interaction $\hat{H}_{\text{SRP}}$ (c.f. equation (2)). The effective Hamiltonian $\hat{H}_{\text{SRP}}^{\text{pol}}$ leads (in the absence of dissipation) to a periodic evolution with the characteristic time $\tau_{\text{int}} = 2\pi/\Lambda$, with $\Lambda = \tilde{g}^2/E_\beta$. If $\Lambda \gg \kappa$ (possible with large enough parametric driving), one finds that the cavity-1 state is strongly nonclassical at $\tau \sim \tau_{\text{int}}/4$, characterized by a Wigner function exhibiting large amounts of negativity, while the MR practically stays in the a pure squeezed state (Fig. 4c). This can be easily understood by considering the effects of the two-photon tunnelling interaction that is mediated by the mechanics, $\hat{a}_2^\dagger \hat{a}_2^\dagger \hat{a}_1 \hat{a}_1 + \text{H.c.}$ As cavity 2 starts in vacuum and cavity 1 has negligible probability for having more than two photons, this term initially transfers two photons from the first to the second cavity in a time $\tau_{\text{int}}/8$. The two-photon Fock state of cavity 2 then gets weakly populated and its Wigner function is reminiscent of a low-amplitude squeezed state (Fig. 4e). After an additional evolution for a time $\tau_{\text{int}}/8$, these two photons return to cavity 1, with an overall π -phase shift. This phase shift of the two-photon component of the cavity-1 state (with respect to the one photon component) leads to negativity in the Wigner function (Fig. 4c).

Next, at the special time $\tau_{\text{int}}/4$ where the cavity-1 state is maximally nonclassical, the parametric drive is rapidly turned off. By using the reverse of our TD protocol (cf. Fig. 4g), this can be done in such a way that the MR returns to its ground state. At this stage, the nonlinear optomechanical interaction is almost completely suppressed: not only is its magnitude greatly diminished, but it is now no longer resonant, such that any residual effects will scale as $g^2/\omega_M \ll \kappa$ (Supplementary Fig. 3). Finally, in the ideal case where internal cavity losses are weak, the nonclassical cavity-1 state is converted perfectly to a propagating mode in the cavity-1 input–output waveguide with an exponential profile. We thus have generated a nonclassical, propagating photonic state, using an underlying weak single-photon optomechanical coupling and the additional linear resource of a parametric drive. We stress that the ability to rapidly turn the mechanically mediated nonlinear interaction on and off is crucial to being able to do this experiment.

Figure 4 | Emergence of negative photonic Wigner functions from enhanced optomechanical coupling. Results illustrating the pulsed protocol described in the main text, for a mechanical parametric drive yielding the optomechanical interaction $\hat{H}_{\text{SRP}}$ (c.f. equation (2)). The effective photon-photon interaction strength $\Lambda = \tilde{g}^2/E_\beta$ sets the characteristic time $\tau_{\text{int}} = 2\pi/\Lambda$. The Wigner function of cavity 1 (2) is plotted in **a-c** (**d-f**) at three characteristic times. Negative (positive) values of the Wigner functions are plotted in blue (red). (**a,d**) Initial state, where cavity 1 is initially displaced by $\alpha_1 = 1$, cavity 2 is in vacuum. The parametric drive is then switched on using the transitionless driving scheme with a short turn-on time $\tau_{\text{on}} = \tau_{\text{int}}/400$ and a Gaussian profile for $r(t)$. The corresponding mechanical amplification strength is plotted in **g**, where **a**, **b** and **c** refer respectively to $\tau = 0$, $\tau = \tau_{\text{int}}/8$ and $\tau = \tau_{\text{int}}/4$. (**c**) Negativity in the cavity-1 Wigner function is maximal at $\tau = \tau_{\text{int}}/4$. As discussed in the main text (and shown in **g**), the parametric drive can then be turned off with the TD scheme, and the cavity-1 state will be emitted into the cavity-1 input-output waveguide, resulting in a propagating photonic state with a negative Wigner function. (**g**) The MR stays in a squeezed state when the parametric drive is on ($\tau_{\text{on}} < \tau < \tau_{\text{int}}/4$). Parameters here are $g = 0.3\kappa$, mechanical damping $\gamma = 10^{-4}\kappa$ and mechanical bath occupancy $\bar{n}_M^{\text{th}} = 0.5$; the parametric-drive strength and detuning are chosen to yield an amplification factor $e^{2r} = 30$ dB and $E_\beta = 2\tilde{g}$. The resulting Kerr-interaction strength is then $\Lambda \approx 2.4\kappa$ and the rate at which the mechanical noise heats the cavities is $\Gamma \sim \kappa/40$. If one reduces the amplification factor to 25 dB, the negativity is lost; this highlights the crucial role of the parametric driving.

Engineered MR response function. While our treatment so far is rigorous, the origin of the enhanced OM interaction may still seem somewhat mysterious. An alternate approach that provides a more intuitive picture, and that is more easily generalized to more complex systems, is based on deriving an effective Keldysh action for the cavity photons. In this approach, one clearly sees that the mechanical resonator mediates a time-non-local effective photon-photon interaction that depends crucially on the retarded Green's functions of the mechanics.

Indeed, by integrating out the mechanical degree of freedom in the Keldysh action obtained for the interaction $\hat{H}_{\text{SRP}}$, one gets an exact effective action describing two distinct time-non-local photon-photon interactions. These interactions can equivalently be captured by writing the equations of motion for the cavity fields; for cavity 1, the interaction term in the

equation of motion is

$$\dot{\hat{a}}_1(t) = \int_{-\infty}^{+\infty} dt' 2i \left\{ \Lambda(t-t') \hat{a}_2^\dagger(t') \hat{a}_1(t') \hat{a}_2(t) + \tilde{\Lambda}(t-t') \hat{a}_1^\dagger(t') \hat{a}_2(t') \hat{a}_2(t) \right\} + \dots \quad (7)$$

with $\Lambda(t) = \frac{1}{2} g^2 G_b^R(t)$ and $\tilde{\Lambda}(t) = \frac{1}{2} g^2 \tilde{G}_b^R(t)$. Here $G_b^R(t) = -i\theta(t) \langle [\hat{b}(t), \hat{b}^\dagger(0)] \rangle$ and $\tilde{G}_b^R(t) = -i\theta(t) \langle [\hat{b}(t), \hat{b}(0)] \rangle$ are, respectively, the non-interacting diagonal and off-diagonal retarded mechanical Green's functions. The role of the parametric drive is to render the off-diagonal element non-zero and amplify $G_b^R(t)$ and $\tilde{G}_b^R(t)$. For large amplification, $G_b^R(t) = \tilde{G}_b^R(t)$ with, in the Fourier domain

$$\tilde{G}_b^R[\omega] = \frac{e^{2r}}{4} \left[\frac{1}{\omega - E_\beta + i\gamma/2} - \frac{1}{\omega + E_\beta + i\gamma/2} \right] \quad (8)$$

In the limit where $E_\beta \gg \kappa, \tilde{g}$, the frequency dependence of the interaction is not important on the relevant energy scales of the system and can be neglected. In this case, the situation is similar to an instantaneous interaction and one recovers the polaron picture of equation (6). This description clearly shows the general idea: to amplify the effective photon-photon interaction, one has to engineer the dynamics, that is, the response function, of the MR.

Discussion

We have studied a two-cavity OM system, showing that parametrically driving the MR exponentially enhances the nonlinear OM interaction. One can thus reach the much-coveted single-photon strong coupling regime starting from an extremely weak bare interaction g . This allows photon blockade and non-Gaussian state generation even when $g \ll \kappa$. This new scheme further benefits from its controllability: one can choose the nature of the nonlinear interaction to amplify as well as modulate in time its strength. Our work suggests more general approaches for enhancing bosonic-mediated interactions and nonlinearities through simple parametric driving.

Methods

Transitionless driving. We give here more details about the 'counterdiabatic' or 'transitionless' driving protocols^{51–53}. These imply controlling the amplitude and the phase of the parametric drive, such that $\lambda(t) = \lambda_0(t) + i\lambda_1(t)$, with $\lambda(0) = 0$ and $\lambda(\tau_{\text{on}}) = \lambda$. Defining the instantaneous unitary transformation $\hat{U}(t) = \exp[\frac{i}{2}r(t)(\hat{b}^2 - \hat{b}^{\dagger 2})]$ with $\tanh 2r(t) = \lambda_0(t)/\Delta$ and considering only the parametrically driven MR, that is, $\hat{H}$ given by equation (1) with $g = 0$, the transformed Hamiltonian is

$$\hat{\tilde{H}}(t) = \hat{U}(t) \hat{H} \hat{U}^\dagger(t) + i\dot{\hat{U}}(t) \hat{U}^\dagger(t) \quad (9)$$

$$= \frac{\Delta}{\cosh 2r(t)} \hat{b}^\dagger \hat{b} + \frac{i}{2} [\lambda_1(t) + \dot{r}(t)] (\hat{b}^{\dagger 2} - \hat{b}^2) \quad (10)$$

Consequently, starting from the mechanical ground state, a parametric drive modulated with $\lambda_1(t) = -\dot{r}(t)$ ensures that (without dissipation) the instantaneous Bogoliubov mode $\hat{\beta}(t) = \cosh r(t) \hat{b} - \sinh r(t) \hat{b}^\dagger$ stays in its ground state. At the end of the protocol, the desired $\hat{\beta}$ mode is thus in a vacuum state. Considering dissipation, we show in the main text that it is still possible to prepare the final Bogoliubov mode $\hat{\beta}$ in the same state as the initial MR state in a time τ_{on} much faster than any other timescales of the system (Fig. 2).

Quantum master equation. To obtain the $g_a^{(2)}$ correlation function and the Wigner function of the cavities state, we use a standard quantum master equation approach⁵⁵. The coherent dynamics is governed by $\hat{H}_{\text{SRP}}$ (c.f. equation (2)) and the coupling of the cavities to zero-temperature baths is described with the Lindbladians $\hat{L} = \kappa D[\hat{a}_1] + \kappa D[\hat{a}_2]$, where $D[\hat{a}] = \hat{a} \cdot \hat{a}^\dagger - \frac{1}{2} \{\hat{a}^\dagger \hat{a}, \cdot\}$. Concerning the mechanical Lindbladian, we consider two configurations: either the Bogoliubov mode is cooled down to its ground state with dissipative squeezing or a TD scheme is used with a MR initially in a thermal state (population $\bar{n}_M^{\text{th}}$). The dissipative squeezing protocol is modelled with the Lindbladian $\gamma_\beta D[\hat{\beta}]$, where γ_β is the coupling rate to the engineered reservoir that squeezes the mechanics, and is used to obtain the results presented in Fig. 3. For these results, we consider a drive on the cavities, $\hat{H}_{\text{drive}} = \epsilon(\hat{a}_1 e^{i\omega_{\text{at}} t} + \hat{a}_2 e^{i\omega_{\text{at}} t}) + \text{H.c.}$; the drive is used to probe the intensity correlations. Meanwhile, the transitionless driving scheme is used in the protocol that leads to negative Wigner functions of the optical mode (c.f. Fig. 4) and

corresponds to a Lindbladian $\gamma(1 + \bar{n}_M^{\text{th}})D[\hat{b}] + \gamma\bar{n}_M^{\text{th}}D[\hat{b}^\dagger]$. The parametric-drive strength is turned on continuously, with $\lambda(t)$ derived above, and we consider an initial coherent state in cavity 1. The density matrix $\hat{\rho}$ in these two situations is then obtained from the quantum master equation

$$\dot{\hat{\rho}} = -i[\hat{H}, \hat{\rho}] + \hat{L}\hat{\rho} \quad (11)$$

The intensity correlations $g_a^{(2)}(0)$ are calculated from the steady-state value of $\hat{\rho}$. For given values of the coupling g and amplification strength e^{2r} , the detuning Δ and the drive frequency are optimized to minimize the intensity correlations. The results are plotted in Fig. 3.

Effective Keldysh action. As explained in the main text, the non-zero response time of the MR results in a time-non-local photon–photon interaction. To describe this physics, we calculate the action of the system in the same interaction picture used for equations (2)–(4), that is, in a frame where the Hamiltonian is not explicitly time-dependent. Since the OM system is driven and subject to dissipation, the Keldysh formalism is well adapted to study this out-of-equilibrium system⁵⁶; a detailed example of the Keldysh formalism in OM systems is presented in ref. 14. In this approach, each annihilation operator used in the Hamiltonian-based description is mapped onto two time-dependent fields: a classical (cl) and a quantum (q) field.

For the cavities ($\sigma = 1, 2$) and MR fields

$$\mathbf{a}_\sigma^\dagger \equiv (a_{\sigma,\text{cl}}^\dagger(t), a_{\sigma,\text{cl}}(t), a_{\sigma,q}^\dagger(t), a_{\sigma,q}(t)) \quad (12)$$

$$\mathbf{b}^\dagger \equiv (b_{\text{cl}}^\dagger(t), b_{\text{cl}}(t), b_q^\dagger(t), b_q(t)) \quad (13)$$

the Keldysh action that describes the full OM system studied in the main text (cf. equation (1)) has the general following form

$$S_{\text{tot}} = \sum_{\sigma=1,2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} dt dt' \left[\mathbf{a}_\sigma^\dagger(t) \hat{\mathbf{G}}_{a_\sigma}^{-1}(t-t') \mathbf{a}_\sigma(t') + \mathbf{b}^\dagger(t) \hat{\mathbf{G}}_b^{-1}(t-t') \mathbf{b}(t') \right] + \frac{g}{\sqrt{2}} \sum_{ijk=\text{cl,q}} \zeta_{ijk} \int_{-\infty}^{\infty} dt \left[a_{2,i}^\dagger(t) a_{1,j}(t) b_k(t) + \text{c.c.} \right] \quad (14)$$

Here $\zeta_{ijk} = 1$ if there is an odd number of quantum fields and 0 otherwise.

In equation (14), the two first terms represent the Gaussian action that governs the non-interacting dynamics (that is, $g = 0$). It involves the non-interacting cavities (MR) Green's functions $\hat{\mathbf{G}}_{a_\sigma}(t-t')$ [$\hat{\mathbf{G}}_b(t-t')$]. Here the most general Green's functions are 4×4 matrices of the form

$$\hat{\mathbf{G}}_b(t) = \begin{pmatrix} \mathbf{G}_b^K(t) & \mathbf{G}_b^R(t) \\ \mathbf{G}_b^A(t) & 0 \end{pmatrix} \quad (15)$$

$$\mathbf{G}_b^R(t) = [\mathbf{G}_b^A(-t)]^T = \begin{pmatrix} \mathbf{G}_b^K(t) & \tilde{\mathbf{G}}_b^K(t) \\ [\tilde{\mathbf{G}}_b^K(t)]^* & [\mathbf{G}_b^K(t)]^* \end{pmatrix} \quad (16)$$

$$\mathbf{G}_b^K(t) = \begin{pmatrix} \mathbf{G}_b^K(t) & \tilde{\mathbf{G}}_b^K(t) \\ -[\tilde{\mathbf{G}}_b^K(-t)]^* & \mathbf{G}_b^K(-t) \end{pmatrix} \quad (17)$$

The retarded Green's functions encode information on the single-particle density of states, and also describe linear response of the system to external perturbations:

$$\mathbf{G}_b^R(t) = -i\theta(t) \langle [\hat{b}(t), \hat{b}^\dagger(0)] \rangle \quad (18)$$

$$\tilde{\mathbf{G}}_b^K(t) = -i\theta(t) \langle [\hat{b}(t), \hat{b}(0)] \rangle \quad (19)$$

The Keldysh Green functions encode information on the distribution functions:

$$\mathbf{G}_b^K(t) = -i \langle \{ \hat{b}(t), \hat{b}^\dagger(0) \} \rangle \quad (20)$$

$$\tilde{\mathbf{G}}_b^K(t) = -i \langle \{ \hat{b}(t), \hat{b}(0) \} \rangle \quad (21)$$

As the action of equation (14) only has linear and quadratic terms in the mechanical fields, the MR can exactly be integrated out⁵⁶. The resulting action that describes only photonic degrees of freedom is

$$S_{\text{eff}} = S_{a_1}^0 + S_{a_2}^0 + \frac{g^2}{8} \int \int_{\mathbb{R}^2} dt dt' [s^R(t, t') + s^K(t, t')] \quad (22)$$

$$s^{R,K}(t, t') = \sum_{ijkl=\text{cl,q}} \zeta_{ijkl}^R s_{ijkl}^{R,K} [s^{R,K}(t, t') + \text{c.c.}], \quad (23)$$

$$s_{ijkl}^{R,K}(t, t') = a_{2,i}^*(t) a_{1,j}(t) \mathbf{G}_b^{R,K}(t-t') a_{2,k}(t') a_{1,l}^*(t') + a_{2,i}^*(t) a_{1,j}(t) \tilde{\mathbf{G}}_b^{R,K}(t-t') a_{2,k}^*(t') a_{1,l}(t') \quad (24)$$

Here $\zeta_{ijkl}^R = 1$ if the interaction term has an odd number of quantum fields and $\zeta_{ijkl}^K = 0$ otherwise, while $\zeta_{ijkl}^K = 1$ if there is both one quantum field between the i, j components and one quantum field between the k, l component, that is, a total of two quantum fields, and $\zeta_{ijkl}^K = 0$ otherwise. The first two terms of equation (22) represent the non-interacting cavities, the third term describes the coherent time-non-local photon–photon interaction while the fourth term describes the extra noise that perturbs the cavities due to their interaction with the MR. As one can see, the diagonal (off-diagonal) MR Green function $\mathbf{G}_b^K(t)$ [$\tilde{\mathbf{G}}_b^K(t)$] mediates a cross Kerr type interaction (two-photon tunnelling) between the cavities. From this effective action, it is clear that modifying the MR Green's functions leads to a modification of the effective photon–photon interaction.

Finally, following ref. 56, one can show that the interaction term s^R in the action of equation (22) is equivalent, in the cavity effective equation of motion, to the contribution highlighted in equation (7). A less-elegant alternative approach to obtain this effective equation of motion is to first solve the Heisenberg–Langevin equation for $\hat{\beta}$. This solution is used to eliminate the $\hat{\beta}$ from the cavities' Heisenberg–Langevin equations. The effective photon–photon interaction, as well as the additional nonlinear noise term then explicitly appear. Another method is to derive an effective Markovian quantum master equation for the optical modes by adiabatically eliminating the MR degrees of freedom⁵⁵. The validity of the adiabatic elimination relies on having a strongly damped MR or a weak ratio $\tilde{g}/E_\beta$. In contrast, the effective Keldysh action derived here is exact and can thus capture non-Markovian effects.

Authors contributions

All authors participated in the conception and planning of the project and were involved in the analysis and interpretation of the results. In particular, M.-A.L. and N.D. led the derivation of theoretical results (with assistance from A.A.C.), and performed all numerical simulations. M.-A.L., N.D. and A.A.C. wrote the manuscript; A.A.C. supervised the project.
