α TAT1 is the major α -tubulin acetyltransferase in mice

& Paul A. Heppenstall¹

Post-translational modification of tubulin serves as a powerful means for rapidly adjusting the functional diversity of microtubules. Acetylation of the ϵ -amino group of K40 in α -tubulin is one such modification that is highly conserved in ciliated organisms. Recently, α TAT1, a Gcn5-related *N*-acetyltransferase, was identified as an α -tubulin acetyltransferase in *Tetrahymena* and *C. elegans*. Here we generate mice with a targeted deletion of *Atat1* to determine its function in mammals. Remarkably, we observe a loss of detectable K40 α -tubulin acetylation in these mice across multiple tissues and in cellular structures such as cilia and axons where acetylation is normally enriched. Mice are viable and develop normally, however, the absence of *Atat1* impacts upon sperm motility and male mouse fertility, and increases microtubule stability. Thus, α TAT1 has a conserved function as the major α -tubulin acetyltransferase in ciliated organisms and has an important role in regulating subcellular specialization of subsets of microtubules.

Microtubules are highly conserved polymerized dimers of α - and β -tubulin, with a broad range of functions in eukaryotic cells such as mitosis, intracellular transport, cellular morphology and motility of cilia¹. The functional diversity of microtubules arises from a number of sources including interaction with microtubule-associated proteins, differential expression of genetically encoded tubulin isotypes and post-translational modification². Of these, post-translational modification of tubulin may be particularly important in tuning the function of microtubules in organelles such as cilia and flagella³.

Acetylation at the ϵ -amino group of K40 of α -tubulin is one such modification that was first described in the flagella of *Chlamydomonas*^{4,5}. Acetylation of α -tubulin is especially enriched in primary and motile cilia⁶, and in neuronal axons⁷, and is used extensively as a marker of these structures. Accordingly, α -tubulin acetylation has been suggested to influence both the assembly and disassembly of the primary cilium^{8,9}, and accelerate kinesin-mediated transport along microtubule tracks in axons¹⁰.

Recently, a number of enzymes have been implicated in the regulation of microtubule acetylation including the deacetylases HDAC6 (ref. 11) and SirT2 (ref. 12), and the acetyltransferases ARD1-NAT1 (ref. 13), ELP3 (ref. 14), San¹⁵, GCN5 (ref. 16) and α TAT1 (refs 9,17,18). Of these, compelling evidence supports a role for α TAT1 as the major α -tubulin acetyltransferase in *Tetrahymena* and *C. elegans*^{9,17}. Genetic ablation of α TAT1 genes in these organisms leads to an almost complete loss of α -tubulin acetylation. In *Tetrahymena*, this in turn slows the growth of cells treated with microtubule depolymerizing agents and increases the rate of depolymerization of axonemes¹⁷. In *C. elegans*, deletion of α TAT1 orthologues MEC17 and α TAT-2, reduces touch sensitivity^{9,17} and disrupts microtubule structure and organization in touch receptor neurons^{18,19}. Importantly, these effects depend upon both the acetyltransferase activity of α -TAT1 and on other as yet unknown functions of this protein¹⁸.

The role of α TAT1 has been less extensively explored in vertebrates. In zebrafish, depletion of the Atat1 orthologue *mec17* results in developmental defects such as reductions in body and head size, hydrocephalus and neuromuscular deficiencies¹⁷. Akin to mammals, acetylated microtubules in zebrafish are located principally in neurons and cilia^{20,21}. Intriguingly, however, it has been reported that while zebrafish *mec17* morphants display an almost complete loss of K40 α -tubulin acetylation in neurons, acetylation of α -tubulin in cilia is preserved¹⁷. This raises the question as to whether an additional acetyltransferase may be responsible for α -tubulin acetylation in vertebrate cilia.

To determine whether α TAT1 functions as an α -tubulin acetyltransferase in mammals, we generated mice with a targeted deletion of Atat1. Strikingly, in homozygous Atat1 knockout mice (Atat1^{-/-}) we were unable to detect tubulin acetylation in embryonic or adult mice across multiple tissues examined. Moreover, at the subcellular level, detectable tubulin acetylation was absent in both the cytoplasm and in cilia. We examined these structures in more detail and found that in the cytoplasm, deletion of Atat1 rendered microtubules more resistant to depolymerization. Primary cilia and motile cilia of the oviduct were, however, present in normal numbers and displayed no abnormalities in their morphology or length. At the whole animal level, Atat1^{-/-} mice were viable, developed normally and displayed no major behavioural phenotype. However, we detected a reduction in mean litter size from male homozygote breedings. In light of the striking absence of detectable acetylation in flagella we examined spermatozoa from these mice and observed deficits in their morphology and motility. Thus, α TAT1 is the major, if not the sole, α -tubulin acetyltransferase in mice and is required for normal sperm flagellar function.

Results

Generation of Atat1^{-/-} mice. To explore the role of α TAT1 and microtubule acetylation *in vivo* in mammals, we generated Atat1 knockout mice. The Atat1 gene is located on chromosome 17 of the mouse genome and consists of 15 exons (Fig. 1a). All annotated protein-coding Atat1 splice variants have the first seven exons in common (ENSMUS accession code G00000024426) and exons 3–7 encode the acetyltransferase domain^{22–25}. We therefore designed a targeting construct whereby exons 1–6 were flanked with *loxP* sites to enable Cre-mediated tissue-specific deletion. A floxed neomycin cassette was also introduced to enable selection of properly targeted ES cells (Fig. 1b). Positive ES cell clones were identified using southern hybridization, and chimeric mice were obtained that were crossed with Flp-expressing transgenic mice to remove the neomycin cassette (termed Atat1^{fl/fl}). Subsequently, Atat1^{-/-} mice were generated by *deleter*-Cre-mediated²⁶ excision of the LoxP-flanked Atat1^{fl/fl} allele. Further crosses were undertaken to remove the Flp and Cre transgenes and experiments were performed on Atat1^{-/-} mice using Atat1^{fl/fl} as controls. Validation of this strategy was achieved using southern hybridization (Fig. 1c) and we were unable to detect Atat1 transcripts by RT-PCR in Atat1^{-/-} mice. Mice were routinely genotyped using PCR (Fig. 1d). Both Atat1^{fl/fl} and Atat1^{-/-} were viable and showed no obvious phenotype.

Absence of K40 α -tubulin acetylation in Atat1^{-/-} mice.

To explore the consequence of Atat1 ablation, we first examined α -tubulin K40 acetylation in multiple adult tissues by immunoblotting with a well-characterized monoclonal antibody that recognizes acetylated K40 on α -tubulin (6-11b-1 (ref. 6)). As shown in Fig. 2 and Supplementary Fig. S1a,b, α -tubulin acetylation is particularly prominent in nervous tissues and testes of control mice, with lower levels present in kidney, lung, ovary and spleen. Liver, pancreas and heart had barely detectable levels of α -tubulin K40 acetylation. Remarkably, in homozygous Atat1 knockout mice we were unable to detect K40 α -tubulin acetylation in the majority of tested tissues (for example, in the brain; Supplementary Fig. S1c), although a very weak signal was evident in heart and liver (Fig. 2b,d). To further quantify α -tubulin acetylation during development we examined immunoblots of E12.5 embryos and embryonic fibroblasts and observed pronounced microtubule acetylation in control animals. Atat1^{-/-} embryos and fibroblasts, however, displayed a complete absence of detectable K40 α -tubulin acetylation (Fig. 2c and Supplementary Fig. S1b). We also investigated whether the lack of K40 α -tubulin acetylation might impact upon expression levels of α -tubulin. As shown in Fig. 2a–c, the total level of α -tubulin protein was not altered in knockout animals.

To increase the sensitivity of immunoblot assays and explore the possibility that ongoing deacetylation might mask compensatory mechanisms regulating α -tubulin acetylation in Atat1^{-/-} animals, we treated mice and fibroblasts with the histone deacetylase inhibitor trichostatin A (TSA). Upon systemic application of TSA in mice we observed a three to fivefold increase in α -tubulin acetylation in tissues from control mice (Fig. 2b,d). In contrast, we were unable to detect an increase in acetylation in any tissue from Atat1^{-/-} mice, including heart and liver. Similarly, in fibroblasts derived from E12.5 embryos, pretreatment with TSA increased α -tubulin acetylation by fivefold in wild-type cells while no acetylation was detected in cells from Atat1^{-/-} mice (Fig. 2c,d).

Microtubule acetylation has been postulated to have an important role in the nervous system²⁷, and it is thus intriguing that Atat1 knockout animals displayed no detectable α -tubulin K40 acetylation in brain, cerebellum and spinal cord. To examine

Figure 1 | *Atat1* alleles. (a) Genomic locus of the *Atat1* gene. Black boxes indicate exons, red boxes indicated targeted exons. (b) Map of the pDTA-*Atat1* targeting construct, targeting allele, LoxP allele and null allele. HA; homology arm, Amp and Neo; ampicillin (bacterial) and neomycin (mammalian) resistance genes. LoxP and FRT sites are indicated. (c) Southern blot analysis of genomic DNA for indicated genotypes. 'kb' indicates kilobases. (d) Genotyping PCR of the wild-type (+/+), heterozygous (+/-) and homozygous (-/-) knockouts.

this further, we sought to measure microtubule acetylation in brains from these animals using an alternative pan-acetylated lysine antibody that may detect several other acetylated lysine residues on α - and β -tubulin *in vitro*²⁸. We thus immunoprecipitated brain extracts from *Atat1*^{-/-} and *Atat1*^{fl/fl} animals with an α -tubulin antibody and immunoblotted eluates with the pan-acetylated lysine antibody. In samples prepared from brain tissue from control animals, we detected a strong signal that was enriched in eluates. Strikingly, however, no signal was detected in *Atat1*^{-/-} extracts (Supplementary Fig. S2, upper panel). Importantly, we observed no difference in the efficiency of immunoprecipitation in these samples, as immunoblots with the α -tubulin antibody were essentially indistinguishable (Supplementary Fig. S2, lower panel).

Cellular properties in *Atat*^{-/-} mice. We next investigated α -tubulin acetylation at the subcellular level by examining two cellular structures that have been demonstrated to contain high levels of microtubule acetylation, sperm flagella and neuronal axons^{27,29}. In sections of testis from control animals we observed strong 6-11b-1 immunofluorescence in the flagellum of sperm and less prominent staining in Sertoli and other cells (Fig. 3a). Consistent with our immunoblotting results, we could not detect any α -tubulin acetylation in testis of *Atat1*^{-/-} mice, although sperm and their flagella were still evident (Fig. 3a). Similarly, in sections of sciatic nerve we observed pronounced α -tubulin acetylation in both large myelinated and small unmyelinated axons of control animals. Sciatic nerve sections from *Atat1*^{-/-} mice were, however, completely negative for 6-11b-1 immunoreactivity (Fig. 3b).

In light of the absence of detectable α -tubulin K40 acetylation in sperm flagella we also examined primary and motile cilia in other cell types. In the hippocampus of *Atat1*^{-/-} mice, α -tubulin acetylation was completely absent, however, primary cilia were present at similar densities to control (*Atat1*^{-/-}; 10.3 ± 0.5 cilia per $1,000 \mu\text{m}^2$, *Atat1*^{fl/fl}; 10.5 ± 0.7 cilia per $1,000 \mu\text{m}^2$) and with comparable morphology and length (*Atat1*^{-/-}; $4 \pm 0.4 \mu\text{m}$, *Atat1*^{fl/fl}; $3.9 \pm 0.2 \mu\text{m}$) (Fig. 3c). Likewise, in oviduct sections, the number, morphology and length of motile cilia were similar between *Atat1*^{-/-} and *Atat1*^{fl/fl} mice (*Atat1*^{-/-} cilium length; $4.5 \pm 0.2 \mu\text{m}$, *Atat1*^{fl/fl}; $4.7 \pm 0.2 \mu\text{m}$, *Atat1*^{-/-} cilia density; 15.7 ± 0.6 cilia per $5 \mu\text{m}$ length of the oviduct, *Atat1*^{fl/fl}; 15.3 ± 0.6 cilia per $5 \mu\text{m}$) (Fig. 3d). Thus the absence of *Atat1* and α -tubulin K40 acetylation does not impact upon the presence or morphological properties of these ciliated organelles.

In addition to axons and cilia, microtubule acetylation is also present at lower levels in the cytoplasm of the majority of cells, including embryonic fibroblasts³⁰. We therefore derived embryonic fibroblasts from E12.5 embryos and measured α -tubulin acetylation by immunostaining cells with the 6-11b-1 antibody. In agreement with all other experiments, detectable α -tubulin acetylation was absent from cytoplasm of fibroblasts derived from *Atat*^{-/-} mice, and immunofluorescence was indistinguishable from background levels (Fig. 3e). We also treated fibroblasts with the histone deacetylase inhibitor TSA to preclude the possibility that physiological deacetylation was concealing low levels of α -tubulin acetylation. In cells from *Atat1*^{fl/fl} mice we observed a pronounced increase in K40 α -tubulin acetylation that was evident on most microtubules

Figure 2 | Microtubule acetylation in *Atat1*^{-/-} mice. (a) Absence of detectable α-tubulin K40 acetylation in *Atat1*^{-/-} mice as determined by immunoblotting of tissues in adults. Total levels of α-tubulin are not changed in *Atat1*^{-/-} animals as detected by immunoblot. (b) *In vivo* application of TSA increases α-tubulin K40 acetylation in control, but not in KO animals. (c) α-tubulin K40 acetylation is undetectable in KO embryos (left panel) and MEFs (right panel). Upon TSA treatment of MEFs the signal of α-tubulin K40 acetylation remained undetectable in KO MEFs. (d) Quantification of (a–c) for representative tissues, *n* > 5. In all images 'Con' indicates *Atat1*^{fl/fl} mice and 'KO' indicates *Atat1*^{-/-} mice. 'DRG' indicates dorsal root ganglion, 'kDa' indicates kilodalton and 'MEF' indicates mouse embryonic fibroblasts.

within each cell. In contrast, we were unable to detect any immunofluorescence in cells from *Atat1*^{-/-} mice (Fig. 3f).

In embryonic fibroblasts, K40 α-tubulin acetylation is particularly enriched in cilia and basal bodies. We thus serum-starved cells and stained them with an antibody against the cilia marker, AcIII (Supplementary Fig. S3a,b). Although *Atat1*^{fl/fl} cells displayed strong α-tubulin acetylation in cilia and basal bodies, fibroblasts from *Atat1*^{-/-} mice showed no traces of detectable K40 α-tubulin acetylation in these structures.

Finally, we sought to determine whether deletion of *Atat1* influences the stability of microtubules in embryonic fibroblasts. Post-translational modifications of tubulin such as acetylation accumulate in stable microtubules³¹, however, it is unresolved as to whether acetylation actively stabilizes microtubules^{30,32–36}. As a measure of microtubule stability, we investigated their resistance to nocodazole, a microtubule depolymerizing drug. Following 30 min of incubation with nocodazole, microtubules in fibroblasts from *Atat1*^{fl/fl} mice were extensively depolymerized (Fig. 4a) and only a few fragments remained (Fig. 4b). On the contrary, microtubules in *Atat1*^{-/-} fibroblasts were still evident after nocodazole pretreatment (Fig. 4a), with obvious fragments of microtubules (Fig. 4b). Quantification of these observations revealed that the number of cells that displayed depolymerized microtubules was significantly reduced in fibroblasts from *Atat1*^{-/-} mice (Fig. 4c), even though these cells contained no detectable K40 α-tubulin acetylation (Supplementary Fig. S3c).

Phenotypic analysis of *Atat1*^{-/-} mice. Despite the apparent absence of microtubule acetylation in *Atat1*^{-/-} animals, mice

were viable and indistinguishable from control litter mates. To investigate these animals in more detail, we performed a series of phenotypic tests to determine whether the high level of acetylated α-tubulin observed in the brain of wild-type mice is required for normal behaviour, and whether the absence of acetylation impacts upon cell proliferation in the hematopoietic system.

We examined neurological behaviour of 8-week-old knockout and control mice (*Atat1*^{-/-} body weight; 28.2 ± 1.2 g, *Atat1*^{fl/fl}, 29.8 ± 1.3 g) with a standard battery of tests (Supplementary Fig. S4). At a first-line observation mice of different genotypes seemed indistinguishable. In a more detailed analysis, *Atat1*^{-/-} mice displayed normal working memory as measured with a Y maze and normal thermal nociception determined with the hot plate test (Supplementary Fig. S4a–c). Muscle strength of all limbs, motor coordination and balance were also unaffected by the loss of *Atat1* (Supplementary Fig. S4d,g). However, in the open field test, *Atat1*^{-/-} mice spent slightly more time in the border area indicating a minor anxiety impairment (Supplementary Fig. S4e,f). This finding was supported by a tendency (though not significant) of *Atat1*^{-/-} mice to spend less time in the open arms of the elevated plus maze (Supplementary Fig. S4h,i).

To determine the effects of microtubule acetylation on cell proliferation we examined the haematopoietic system. Inspection of peripheral blood from these animals showed comparable levels of white blood cells in knockout and control animals (Supplementary Fig. S5a). The number of red blood cells and haemoglobin levels were also within normal range (Supplementary Fig. S5b,c) as was the number of platelets

Figure 3 | Cellular distribution of microtubule acetylation in *Atat1*^{-/-} mice. (a) Testis sections stained with antibodies against acetylated K40 α -tubulin (green), deetyrosinated tubulin (red), and DAPI (blue). Sperm flagella display no detectable K40 α -tubulin acetylation in *Atat1*^{-/-} mice. Scale bar, 80 μ m. (b) Sciatic nerve cross sections stained with antibodies against acetylated K40 α -tubulin (green), and myelin basic protein (red), scale bar, 20 μ m. (d) H&E staining of oviduct sections showing motile cilia; scale bar, 20 μ m. (e) Mouse embryonic fibroblasts stained with antibodies against β -tubulin (green), acetylated K40 α -tubulin (red) and DAPI (blue); scale bar, 20 μ m. Inset (size 2.3 μ m) shows partially acetylated microtubules. (f) Mouse embryonic fibroblasts stained with the same antibodies as in (e) but after 4 h incubation with Trichostatin A (TSA); scale bar, 20 μ m. Inset (size 20 μ m) shows highly acetylated microtubules. In all images, 'Control' indicates *Atat1*^{fl/fl} mice and 'KO' indicates *Atat1*^{-/-} mice.

(Supplementary Fig. S5d). As we also did not detect any visible developmental defect in *Atat1*^{-/-} mice, this indicates that cell proliferation is not grossly affected by deletion of *Atat1*.

Finally, we considered whether progeny number and hence fertility was altered in *Atat1*^{-/-} mice. Heterozygous crossings produced litters with the appropriate Mendelian ratios of homozygote, heterozygote and control pups. Intriguingly, however, we observed a significant decrease in litter size from

Atat1^{-/-} compared with control *Atat1*^{fl/fl} crosses (*Atat1*^{-/-}; 7.3 ± 0.5 offspring per cross, *Atat1*^{fl/fl}; 8.9 ± 0.5 , $P = 0.04$, Student's *t*-test). We investigated the contribution of male fertility to this phenotype by crossing male *Atat1*^{-/-} mice with female *Atat1*^{fl/fl} mice. Again litter size was significantly reduced (*Atat1*^{-/-} males; 7.2 ± 0.5 offspring per cross, *Atat1*^{fl/fl} males; 8.9 ± 0.5 , $P = 0.03$, Student's *t*-test) and the percentage of matings, which resulted in a litter was also lower (*Atat1*^{-/-}

Figure 4 | Microtubules in *Atat1*^{-/-} fibroblasts are more resistant to nocodazole-induced depolymerization. *Atat1*^{-/-} and *Atat1*^{fl/fl} MEFs (labelled 'KO' and 'Control', respectively), were stained with α -tubulin antibody after a 30-min incubation with nocodazole. **(a)** Low-magnification images demonstrating that microtubules are extensively depolymerized in control cells (asterisk) while microtubules from *Atat1*^{-/-} MEFs are resistant. **(b)** High magnification images showing that fragments of microtubules only occasionally remain in control cells (arrow), while the majority of the microtubule cytoskeleton is present in knockout cells. **(c)** Quantification of the proportion of fully depolymerized and fragmented microtubules in *Atat1*^{-/-} and *Atat1*^{fl/fl} MEFs, $n = 200$ cells from three different experiments.

males 64%, *Atat1*^{fl/fl} males 70%). Collating this information revealed that the total number of offspring born from each mating was reduced to 4.6 ± 1 for male *Atat1*^{-/-} compared with 7.4 ± 0.9 for male *Atat1*^{fl/fl} mice ($P = 0.047$ from 32 crosses). Thus, deletion of *Atat1* impacts upon male mouse fertility.

Abnormalities in spermatozoa from *Atat1*^{-/-} mice. On account of the high level of tubulin acetylation in sperm flagella, and the prominent role of tubulin modifications in cilia²⁹, we focused our analysis of mouse fertility on spermatogenesis and axoneme structure and function in *Atat1*^{-/-} mice. We first measured testes and epididymis size, and observed a significant decrease in the weight of these tissues upon *Atat1* deletion (*Atat1*^{-/-} normalized testis weight; $0.27 \pm 0.011\%$ of body weight, *Atat1*^{fl/fl}; $0.32 \pm 0.007\%$, $P = 0.003$, Student's *t*-test. *Atat1*^{-/-} normalized epididymis weight; $0.13 \pm 0.008\%$, *Atat1*^{fl/fl}; $0.17 \pm 0.01\%$, $P = 0.02$, Student's *t*-test, all animals were 8 weeks old). In addition, the number of spermatozoa extracted from cauda epididymis was also significantly reduced in *Atat1* knockout mice (*Atat1*^{-/-}; $17.5 \times 10^6 \pm 1.3 \times 10^6$ per ml, *Atat1*^{fl/fl}; $26.9 \times 10^6 \pm 1 \times 10^6$ per ml, $P < 0.001$, Student's *t*-test). To examine this further, we undertook a histological examination of testis and observed that H&E stained sections were indistinguishable in *Atat1*^{-/-} and *Atat1*^{fl/fl} mice (Fig. 5a). As a more sensitive measure of cell death in spermatogenesis, we also performed TUNEL staining. TUNEL-positive apoptotic cells were occasionally found in the basal portions of the seminiferous tubules in wild-type mice. *Atat1*^{-/-} mice, however, showed increased cell death in seminiferous tubules that was not only present at the basal portion, but throughout the tubules including the luminal side (Supplementary Fig. S6). Thus, *Atat1* deletion may have minor effects on the early development of spermatogonia or their maturation into spermatozoa.

We next assessed morphological characteristics of mature spermatozoa isolated from cauda epididymis and observed striking differences in their structure. Concomitant with high levels of tubulin acetylation in the flagella of wild-type sperm, these structures were often disrupted in *Atat1*^{-/-} mice and

characterized by the presence of a cytoplasmic droplet attached to the annulus of the tail (Fig. 5b, *Atat1*^{-/-}; $31.34 \pm 2.62\%$, *Atat1*^{fl/fl}; $7.79 \pm 1.53\%$, $P < 0.00001$, Student's *t*-test). Cytoplasmic droplets are associated with the impaired maturation of sperm and have been implicated in the process of cytoplasm exclusion and flagellum growth³⁷. Although cytoplasmic droplets were occasionally present in spermatozoa from control animals, their occurrence was dramatically increased in sperm from *Atat1*^{-/-} mice (Fig. 5b). Moreover, flagella length was also significantly decreased in spermatozoa from *Atat1* knockout mice, especially in those cells with a cytoplasmic droplet (*Atat1*^{-/-} without cytoplasmic droplet; $99.99 \pm 0.72 \mu\text{m}$, *Atat1*^{-/-} with cytoplasmic droplet; $97.94 \pm 0.94 \mu\text{m}$, *Atat1*^{fl/fl}; $106.01 \pm 0.52 \mu\text{m}$, $P < 0.001$, Student's *t*-test).

To determine whether these morphological defects impact upon the function of spermatozoa we investigated sperm motility. Spermatozoa extracted from *Atat1* knockout mice displayed significantly lower motility than control sperm. This was evident as a reduction in the number of sperm showing progressive motion, while proportions of stationary cells displaying twitching movement were similar (Fig. 5c). We characterized sperm motility further by measuring flagella beat properties. Beat lateral amplitude was reduced in *Atat1* knockout mice (*Atat1*^{-/-}; $22.85 \pm 1.1 \mu\text{m}$, *Atat1*^{fl/fl}; $27.44 \pm 0.9 \mu\text{m}$, $P = 0.003$, Student's *t*-test) as was curvilinear velocity (*Atat1*^{-/-} $266.5 \pm 6.0 \mu\text{m s}^{-1}$, *Atat1*^{fl/fl} $291.11 \pm 7.6 \mu\text{m s}^{-1}$, $P = 0.02$, Student's *t*-test) indicating that α TAT1 is required for normal flagella motion in spermatozoa.

Finally, we examined electron micrographs of sperm flagella from sections of cauda epididymis to determine whether *Atat1* deficiency influences the ultrastructural organization of sperm axonemes. Motile cilia possess a characteristic 9 + 2 organization of axoneme microtubules consisting of 9 outer microtubule doublets and 2 central single microtubules³⁸, and this organization has been shown to be disrupted in the absence of other tubulin modifications such as polyglutamylolation³. In sperm flagella of α TAT1, knockout mice we observed a normal 9 + 2 distribution (Fig. 5d), indicating that α TAT1 and microtubule

Figure 5 | Spermatozoa abnormalities in *Atat1*^{-/-} mice. (a) H&E staining of testis from *Atat1*^{-/-} and *Atat1*^{fl/fl} mice showing no significant difference between the two genotypes. Scale bar, 50 μ m. (b) A larger proportion of *Atat1*^{-/-} spermatozoa contain a cytoplasmic droplet ($n = 8$ of each genotype). Boxed images show representative examples of spermatozoa. An asterisk marks the position of the cytoplasmic droplet and the inset shows the droplet enlarged. Scale bar, 10 μ m. (c) Stacked bar graph showing the percentage of spermatozoa that are stationary, display twitching movement, or have progressive forward motion. Spermatozoa from *Atat1*^{-/-} mice display less progressive motility. (d) Electron micrographs of sperm flagella from control and *Atat1*^{-/-} mice. Longitudinal (left panels) and cross sections (right panels) indicate that the 9 + 2 distribution of microtubules is intact in *Atat1*^{-/-} mice. Scale bar, 100 nm. In all images, 'Control' indicates *Atat1*^{fl/fl} mice and 'KO' indicates *Atat1*^{-/-} mice.

acetylation exert their effects on flagella structure and function via another mechanism.

Discussion

Here we have examined the consequence of genetic ablation of *Atat1* on microtubule acetylation and mouse physiology *in vivo*. We demonstrate that K40 α -tubulin acetylation is essentially undetectable in *Atat1*^{-/-} mice suggesting that α TAT1 is the major mammalian K40 α -tubulin acetyltransferase. Mice are viable and display no major deficits in development, behaviour or adult homeostasis. We did, however, observe a decrease in progeny number from male homozygote *Atat1* knockout mice, and deficiencies in the morphology and motility of sperm. As α -tubulin acetylation is particularly enriched in the flagella of sperm, these data suggest that *Atat1* may have a role in flagellar function.

We were unable to detect acetylated K40 immunoreactivity in *Atat1*^{-/-} mice across multiple tissues from adult and embryonic mice as well as in cells derived from these mice. Similarly, treatment of mice or cells with the histone deacetylase inhibitor to block endogenous α -tubulin deacetylation did not unmask any low level acetylation present in *Atat1*^{-/-} mice. Thus, in contrast to an earlier report that α -tubulin acetylation persists in zebrafish cilia upon depletion of the *Atat1* orthologue *mec17* (ref. 17), our data suggest that *mec17* may have not been fully depleted in zebrafish, and that in mice, α TAT1 is likely the major α -tubulin acetyltransferase in both cilia and cytoplasm. Several other

candidate acetyltransferases have also been implicated in α -tubulin acetylation, including ARD1-NAT1 (ref. 13), ELP3 (ref. 14) and GCN5 (ref. 16). The lack of detectable K40 α -tubulin acetylation in α TAT1^{-/-} mice reported here indicates that these other enzymes are not able to rescue deficiency of α TAT1, and therefore probably do not acetylate α -tubulin directly *in vivo*. They may, however, have a role in regulating the expression or activity of α TAT1 and exert their effects on microtubule acetylation indirectly.

Despite the apparent absence of α -tubulin acetylation in *Atat1*^{-/-} mice, we did not observe any gross defects in the development or homeostasis of these mice. Similarly we could not detect any deficits in cellular structures, which normally express high levels of acetylated α -tubulin, such as axons or primary and motile cilia. This is in broad agreement with previous studies demonstrating that both *Chlamydomonas* and *Tetrahymena* have no observable phenotype upon genetic manipulation of native α -tubulin to a non-acetylatable form in these organisms^{39,40}. Moreover, disruption of the α -tubulin deacetylase HDAC6 in mouse results in hyperacetylation of α -tubulin, but does not affect ES cell proliferation or differentiation⁴¹, or produce substantial phenotypes in mice³⁰. Collectively, our data indicate that cells and organisms are able to tolerate considerable shifts in the degree of tubulin acetylation.

Intriguingly, we did observe that deletion of *Atat1* renders microtubules more resistant to depolymerization in cultured fibroblasts. As nocodazole prevents microtubule growth, but does not perturb existing microtubules, our data show that there are

more long-lived (stable) microtubules in KO cells. In support of these findings, we have previously reported that small interfering RNA-mediated depletion of α TAT1 increases microtubule stability and reduces microtubule dynamics³⁶. Together these data imply that although acetylated α -tubulin accumulates in stable microtubules³¹, it is not required to actively stabilize microtubules. Indeed, it is likely that α TAT1 has additional roles at microtubules beyond its acetyltransferase function that may serve to regulate dynamic instability and other properties of microtubules^{36,42}.

It is perhaps surprising that *Atat1* knockout mice displayed only minor differences in neurological behaviour. α -tubulin acetylation has been suggested to influence kinesin-mediated transport¹⁰, and increase sensitivity of microtubules to severing in neuronal axons⁴³, although these effects may be more dependent upon other tubulin modifications such as tyrosination^{44,45} and polyglutamylation⁴⁶. Migration and maturation of cortical neurons during development have also been reported to be dependent upon tubulin acetylation^{14,47}, and depletion of *mec17* in zebrafish leads to substantial neurological deficits¹⁷. We performed behavioural analysis on 8-week-old naïve mice and found only a very mild anxiety phenotype in the open field test. It is possible that further phenotypes only become apparent in older mice or after challenge such as that resulting from disease or pathology. It is, however, clear from our analysis that *Atat1*^{-/-} mice represent a powerful tool with which to examine the function of microtubule acetylation *in vivo*, and in depth analysis of these mice in appropriate models may uncover novel phenotypes.

We observed a decrease in litter size from homozygote crosses of *Atat1*^{-/-} mice. We reasoned that this may have its basis in altered fertility because we detected no developmental defects in knockout mice and heterozygote crosses produced appropriate Mendelian ratios of *Atat1*^{-/-} progeny. We focused our analysis on the male reproductive system as testis has one of the highest levels of microtubule acetylation in control mice. Accordingly, we observed that similar decreases in litter size were also apparent from male *Atat1*^{-/-} to female *Atat1*^{fl/fl} crosses. We found minor differences in the number of sperm produced by *Atat1*^{-/-} mice and more prominent effects on their morphology and motility. Of note, these deficits did not arise from gross structural abnormalities of axoneme organization as has been demonstrated for other tubulin modifications such as polyglutamylation³. Rather, we speculate that subtle differences in microtubule function such as intraflagellar transport may account for the shorter flagella in *Atat1*^{-/-} mice and subsequent deficits in motility⁴⁸.

In summary, we demonstrate that *Atat1* is essential for microtubule acetylation *in vivo* in the mouse. We observed no major deficits in the development or physiology of these mice, however, animals were sub-fertile and displayed abnormal sperm morphology and motility. *Atat1*^{-/-} mice thus represent the first *in vivo* mammalian model for α -tubulin acetylation deficiency and as such could be a valuable tool for exploring the role of this modification in pathology and disease.

Methods

Generation of the *Atat1* null allele. The *Atat1* targeting strategy was designed to allow Cre-mediated excision of the first six exons of the *Atat1* gene that code for the putative acetyltransferase domain of α TAT1. The *Atat1* gene-targeting vector (*pDTA-Atat1*) contained a *loxP* site 5' of exon 1, a neomycin resistance (*neo*^r) gene flanked with two *frt* sites, and a *loxP* site (*neo*^r-*frt2-loxP* cassette) located 3' of exon 6.

The targeting construct was transfected into A9 ES cells (A. Wutz, manuscript in preparation). Southern blotting of individual ES cell clones was used to identify homologous recombinants. Positive clones were injected into 8-cell stage embryos to generate mice heterozygous for the targeted allele. Mice were first crossed with FLP-expressing transgenic mice to remove the *frt* flanked *neo*^r cassette and then to *deleter*-Cre mice. These genetic manipulations resulted in the

generation of *Atat1* *LoxP* alleles (Fl allele), and *Atat1* null alleles, respectively. All analysis was performed on mice that did not carry the FLP^{ER} or *Del-Cre* alleles.

Mouse genotype was verified by PCR using primers CCTCTCCCAC-TATTGTCTCTCATT (forward for wild-type and *LoxP* (fl) allele), GTATGCCCTTGATGGTGTGTCCCTG (forward for the null allele) and CCTGGAGATGGGTGCATATAAAC (reverse for all). The presence of the Neo cassette (targeted allele) was verified using the forward primer TCCTCCAGCGCGGGATCTCATG together with the previously mentioned reverse primer. The presence of the FLP transgene was determined with the following primers; CCCATTCCATGCGGGTATCG and GCATCTGGGAGATC ACTGAG. The presence of Cre recombinase was checked with primers GCACGTATTCGACCAGGTT and GAGTCATCCTTAGCGCCGTA.

Mice were bred and maintained at the EMBL Mouse Biology Unit, Monterotondo, in accordance with Italian legislation (Art. 9, 27, Jan 1992, no 116) under licence from the Italian Ministry of Health. *Atat1* conditional alleles have been deposited in the European Mutant Mouse Archive (www.emmanet.org).

Biochemistry and immunohistochemistry. All experiments, except Fig. 2c and Fig. 3e,f, were performed on tissue from 8-week-old mice. Mice were killed by cervical dislocation before the tissues were harvested. For the TSA-induced microtubule acetylation test, animals were injected intraperitoneally with 10 mg kg⁻¹ of Trichostatin A (9950, Cell Signaling) and killed 1 h later. For western blotting, all tissues were homogenized and lysed in buffer containing 150 mM NaCl and 1% Triton X-100. Ten microgram of lysates were used for gel electrophoresis. Western blotting was performed with the following primary antibodies: anti- α -tubulin (T5168, Sigma), anti-acetylated- α -tubulin (T7451, Sigma), anti-actin (MAB1501, Chemicon), anti-pan-acetylated lysine (AB3879, Chemicon) and the following secondary antibodies: anti-mouse-HRP linked (NA931V, GE Healthcare) and anti-rabbit-HRP linked (NA934V, GE Healthcare). Detection of western blots was performed using the ECL Western blot detection reagent (RPN2106, GE Healthcare). Immunoprecipitation was performed overnight in lysis buffer with the anti- α -tubulin antibody and G protein sepharose beads (17-0618-01, GE Healthcare). Subsequently, proteins were eluted after three washings performed in the same lysis buffer.

For histology, oviducts were fixed in 4% paraformaldehyde immediately after dissection, while for the testes and sperm from cauda epididymis modified Davidson's fluid (2% formaldehyde, 35% EtOH, 10% acetic acid) was used. The tissues were subsequently embedded in paraffin, sectioned and stained with hematoxylin and eosin. Images were taken on a Leica DM 6000B microscope. Sperm morphological parameters were quantified using ImageJ.

To detect apoptotic cells in PFA-fixed testes we used the DeadEnd Fluorimetric TUNEL System (TB235, Promega) following the manufacturer's instructions.

Immunostainings of brain, testes and sciatic nerves was also performed on paraffin sections after fixation with PFA. Following rehydration, antigen retrieval was performed with 10 mM sodium citrate (pH 6) at boiling temperature for 10 min. Subsequently, sections were permeabilized (0.3% Triton X-100), blocked (5% goat serum) and stained with anti-acetylated- α -tubulin, anti-myelin basic protein (MAB386, Chemicon), anti-detyrosinated- α -tubulin (AB3201, Millipore), anti- β -tubulin (2146S, Cell Signaling) or anti-adenylyl cyclase III (sc588, Santa Cruz Biotechnology). Samples were examined on a Leica SP5 confocal microscope using a $\times 20$ objective. Processing of images, quantification of fluorescent signal and cilia length quantification were performed using ImageJ.

Immunocytochemistry was performed on E 12.5 mouse embryonic fibroblasts (MEFs, passage 2), as previously described⁴⁹. Microtubules were stained using anti- α -tubulin (T5168, Sigma), anti- β -tubulin (2146S, Cell Signaling), and anti-acetylated- α -tubulin (T7451, Sigma) antibodies. For cilia staining, MEFs were serum-starved in Optimem for 48 h before the fixation. For nocodazole-caused microtubule depolymerization test, MEFs were incubated in 10 μ M nocodazole (M1404, Sigma) for 30 min before fixation. For the TSA treatment cells were incubated for 4 h with 5 μ M TSA (9950, Cell Signaling) before harvesting. All cells were imaged at the Leica SP5 confocal microscope using $\times 40$ and $\times 63$ objectives. The images were processed using ImageJ.

Sperm analysis. Caudae epididymes from *Atat1*^{fl/fl} and *Atat1*^{-/-} mice were dissected and aliquots of sperm suspension were used for counting as previously described⁵⁰. Sperm was incubated and analysed in DMEM supplemented with 10% FBS, 75 mg l⁻¹ penicillin, 50 mg l⁻¹ streptomycin, 0.01 mM EDTA, 0.23 mM sodium pyruvate. Sperm motility assays were performed 1 h after dissection on an Axiovert 200 microscope (Zeiss), recording at 25 frames per second. Sperm curvilinear velocity was measured using ImageJ and computer-assisted sperm analyser software, CASA⁵¹. Beat amplitude was measured using the BeatAnalysis Toolkit⁵².

Conventional electron microscopy. Caudae epididymes were fixed with a mixture of 2% (w/v) PFA, 2% (w/v) glutaraldehyde (TAAB) in 0.1 M sodium cacodylate buffer (Agar), pH 7.4, post-fixed with 1% (w/v) OsO₄ supplemented with 1.5% (w/v) potassium ferrocyanide, dehydrated in Ethanol and infiltrated with propylene oxide (Agar)/Epon (Agar) (1:1) followed by Epon embedding. Ultrathin sections were cut with an Ultracut S microtome (Leica), counter-stained

with Lead Citrate and monitored with a transmission electron microscope (TEM) Jeol 1010. Representative images were obtained using a Gatan MSC 791 CCD camera (Gatan).

Behavioural and haematological analysis. Behavioural tests were performed on 8-week-old male mice (body weight indicated earlier). All the tests were carried out according to standard procedures described by Eumorphia.

Briefly, the Y maze was used to test working memory by detecting the entry into alternating arms of the maze. Alternations are determined as successive entries into each of the three arms as on overlapping triplet sets. Arm exit is defined when all four paws have left the length of the arm. Spontaneous alternation preference is defined as the ratio of actual to possible alternations $\times 100$ and was used as the measure of working memory. Latency to exit the starting arm of the Y maze was scored as an index of emotionality.

The hot plate was used to test nociceptive responses to high temperatures. The temperature of the hot plate was set to 55 °C and the latency to the first withdrawal was measured. The grip strength test was used to assess muscle strength of combined forelimbs-hind limbs. A Bioseb grip strength meter apparatus was used. The RotaRod test was used to measure the latency it takes for a mouse to fall off the rod that is rotating under continuous acceleration (from 4 to 40 r.p.m.). An average of four independent trials per mouse was calculated. The open field test was used to assess ambulation in mice as a measurable output of a combination of anxiety and exploratory drive. Locomotor drive of tested animals was comparable to those in the home cage. Elevated plus maze test was used to test the anxiety behaviour.

Analysis of peripheral blood was performed using the HV2729 HV950FS Hemavet Unit, following the manufacturer's instructions. Eight-week-old male mice were used.

Statistical analysis. Statistical significance was determined using the Student's *t*-test. All values are expressed as mean $\pm$ s.e.m.
