One-dimensional defects in graphene have a strong influence on its physical properties, such as electrical charge transport and mechanical strength. With enhanced chemical reactivity, such defects may also allow us to selectively functionalize the material and systematically tune the properties of graphene. Here we demonstrate the selective deposition of metal at chemical vapour deposited graphene's line defects, notably grain boundaries, by atomic layer deposition. Atomic layer deposition allows us to deposit Pt predominantly on graphene's grain boundaries, folds and cracks due to the enhanced chemical reactivity of these line defects, which is directly confirmed by transmission electron microscopy imaging. The selective functionalization of graphene defect sites, together with the nanowire morphology of deposited Pt, yields a superior platform for sensing applications. Using Pt-graphene hybrid structures, we demonstrate high-performance hydrogen gas sensors at room temperature and show its advantages over other evaporative Pt deposition methods, in which Pt decorates the graphene surface non-selectively.

Graphene, an atomically thick sp^2 -bonded carbon membrane, has excellent electrical and optical properties such as high charge carrier mobility¹ and tunable optical absorption². Owing to these excellent properties, graphene has emerged as a promising candidate in applications such as optoelectronics³ and high-frequency electronics⁴. Graphene also has promising properties towards high-speed and ultra-sensitive gas/vapour sensors, because every atom in graphene is a surface atom and it can readily respond to environmental changes^{5–7}. For successful applications, large-area high-quality graphene growth has been intensively studied, and significant advances have recently emerged^{8–11}. Among them, chemical vapour deposition (CVD) has achieved successful growth of high-quality, polycrystalline monolayer graphene on metals^{9,12}. Although it can be generally of good quality, CVD graphene still has numerous synthesis-related defect structures, especially one-dimensional (1D) line defects. Typically, CVD graphene synthesis yields a polycrystalline graphene structure with grain sizes in the order of a few micrometres^{9,13–15}. Moreover, the transfer process of graphene inevitably renders wrinkles^{16–18}, folds¹⁹ and cracks²⁰ in CVD graphene. These line defects in CVD graphene can play important roles in determining CVD graphene's electrical and mechanical properties, as shown in recent studies^{14,15,21–23}.

The chemical properties of graphene defects are also of great interest. Generally, the pristine graphene lattice site is rather chemically inert; however, the introduction of atomic-scale defects in graphene can significantly modify its chemical and magnetic properties^{24,25}. Previous theoretical studies shed light on enhanced chemical reactivity of 1D line defects, especially grain boundaries, in CVD graphene^{26–28} but the available experimental study on this subject is limited. The chemical functionalization at these reactive sites would be an interesting way to modify the physical and chemical properties of CVD graphene.

In this paper, we demonstrate the selective deposition of metal at the line defects of polycrystalline CVD graphene, notably grain boundaries, via atomic layer deposition (ALD). ALD allows us to

deposit Pt predominantly at graphene's grain boundaries, folds and cracks due to the enhanced chemical reactivity at these defect sites. Transmission electron microscopy (TEM) directly confirms that most of the Pt deposition sites coincide with graphene line defects. By density functional theory (DFT) calculations, we confirm that a graphene grain boundary has higher chemical reactivity compared with the pristine lattice due to local strained C–C bonding. As the number of ALD cycles increases, Pt nanoparticles deposited along the defect sites coalesce and adopt nanowire morphology. The optical transmittance and electrical conductivity of the obtained graphene–Pt hybrid structures are studied as a function of Pt deposition. Finally, we demonstrate high-performance hydrogen gas sensors using Pt ALD graphene hybrid structures and show its advantages over evaporative Pt deposition methods, in which Pt decorates the surface of graphene non-selectively, regardless of defect locations. The selective functionalization of graphene defect sites, with the nanowire morphology of deposited Pt, yields a superior platform for sensing applications.

Results

Selective deposition of Pt at graphene line defects. Previous ALD studies on carbon nanotubes and graphene have focused on the deposition of high- κ dielectric materials for transistor applications. For this purpose, uniform deposition of the dielectric material is desirable. Without surface functionalization, the carbon nanotube and graphene surface is inert and the metal oxide will grow only at defect structures such as graphite step edges (or graphene edges)^{29–31}. On the other hand, surface functionalization can be used to deposit a uniform metal oxide film on carbon nanotube and graphene surfaces^{29,32–34}. Metal deposition by ALD has recently gained much attention^{35–37} and, notably, selective metal (Pt) growth at the step edges of highly ordered pyrolytic graphite (HOPG) also has been demonstrated³⁸. The HOPG step edges serve as Pt nucleation sites due to their higher chemical reactivity compared with the inert basal plane, which arise from a combination of dangling

Figure 1 | Selective Pt growth by ALD on one-dimensional defect sites of polycrystalline CVD graphene. (a) Schematic of selective Pt growth on 1D defects in CVD graphene. Various line defects, such as grain boundaries, cracks and folded structures are present in CVD graphene. By utilizing atomic layer deposition, metal can be selectively deposited at the one-dimensional defect sites in graphene. The graphene–metal hybrid structure can be obtained through this process. (b) SEM images of CVD graphene on a glass substrate after 500 ALD cycles of Pt deposition. Pt growth shows the predominant line shape. Scale bar, 2 μm . bonds and functional groups. A similar concept can be applied to CVD graphene. When the ALD process is utilized, metal will be selectively deposited at the 1D line defects in CVD graphene due to their enhanced chemical reactivity. Figure 1a shows a schematic of selective metal growth at 1D defect sites of polycrystalline CVD graphene by ALD. From this process, we expect to obtain a graphene-metal hybrid structure, where a network of metal nanowires decorates graphene line defects. Such a structure may be of interest for transparent electrodes and sensors, for which the control of conductivity across grain boundaries is important.

We synthesize polycrystalline CVD graphene using previously reported growth conditions, and transfer graphene to a glass slide with a poly (methyl methacrylate) (PMMA) support⁹. On these prepared graphene samples, we perform Pt ALD and systematically study the evolution of Pt deposition as a function of the number of ALD cycles. (See the Methods Section for the detailed sample preparation and Pt ALD process.) After the Pt deposition, scanning electron microscopy (SEM) imaging is utilized to check Pt deposition on CVD graphene (Fig. 1b,c). Figure 1b shows CVD graphene after 500 cycles of Pt ALD. The Pt-deposited sites are predominantly arranged in a nanowire shape. The distance between these line features are on the order of micrometres, which is on the same order of the graphene grain size in CVD graphene^{13,19}. Additional ALD cycles give higher Pt coverage on CVD graphene. Figure 1c shows the Pt deposition on graphene after 1,000 ALD cycles. We note that, other than line features, there are isolated Pt particles in CVD graphene samples. The isolated Pt particle deposition can be mainly attributed to Pt nucleation at point defects in prepared graphene samples. Possible surface contamination (mainly PMMA residues) can be eliminated from the main source of point Pt nucleation since controlled experiments with PMMA-covered graphene do not induce Pt nucleation on the surface with an identical ALD process (see Supplementary Fig. 1).

Although SEM images confirm the line-shaped morphology of ALD Pt on CVD graphene, it does not give us spatially resolved information on whether the Pt deposition sites correspond to the graphene defects. To directly confirm the selective growth of Pt at the graphene line defects, we employ TEM. After preparing suspended graphene TEM samples, we perform Pt ALD for TEM characterization with similar ALD conditions. Figure 2 shows the suspended graphene sample on a holey carbon TEM grid. The sample area outside the circles has a carbon support while inside the circle is the freestanding graphene (Fig. 2a).

The TEM image in Fig. 2a confirms the distinct growth of Pt along line features with scattered point Pt nucleation, which is consistent with SEM imaging. It also confirms that the line features along which Pt growth occurs correspond to grain boundaries in the graphene. We acquire images around Pt line decoration at higher magnifications to obtain graphene lattice information as shown in Fig. 2b–d. The fast Fourier transforms (FFTs) of these images reveal that graphene has a relatively rotated lattice across the line features, confirming the presence of graphene tilt grain boundaries (Fig. 2e–g). Additional TEM images obtained in other areas also confirm that many of the Pt line features are originated from grain boundaries in CVD graphene (see Supplementary Figs 2–4). We can also identify the rotational mismatch angles of each graphene grain from FFT analysis as shown in Fig. 2a.

We compare Pt nuclear densities at the graphene grain boundaries and inside the grains. Although we observe preferential growth of Pt at line defects, we also observe scattered Pt nucleation inside the grains, possibly due to graphene point defects or residues on the graphene surface. With TEM images of 300 ALD cycle samples, we find that the average distance between

Pt nucleation is ~ 11 nm at graphene grain boundaries. If we assume the effective width of grain boundaries as 1 nm ^{13,14}, this value corresponds to the Pt nucleation density of $8.8 \times 10^{-2}\text{ nm}^{-2}$. On the other hand, we find that the Pt nucleation density is $2.0 \times 10^{-4}\text{ nm}^{-2}$ inside the graphene grains (Supplementary Table 1). This is 440 times a lower value compared with that at the grain boundaries, which clearly demonstrates the preferential Pt nucleation effect at the graphene grain boundaries. Raman spectroscopy can be used to estimate the defect density in a graphene sample³⁹, and the observed Pt nucleation density inside the grains, $2.0 \times 10^{-4}\text{ nm}^{-2}$, is consistent with an estimated defect density in a high-quality graphene sample (Supplementary Fig. 5; Supplementary Note 1).

Atomic resolution TEM imaging can be also performed at these functionalized graphene grain boundaries. Figure 3a clearly shows Pt decoration along a line feature after 300 ALD cycles. Magnified images at the upper and lower parts of the graphene lattice show that the two areas have a misaligned graphene lattice, also confirming the presence of a tilt grain boundary at the Pt line decoration. In that area, the upper (Fig. 3b) and lower (Fig. 3c) parts of the graphene lattice have a relative misorientation of 13° . Pt nanoparticles have a diameter around 10 nm and some particles are successfully inter-connected. No visible hole is observed in graphene around grown Pt nanoparticles, and the suspended graphene sample maintains its structural integrity even after 1,000 ALD cycles. Together with Raman spectroscopy measurements, these observations support that the utilized ALD process does not introduce extra defects in graphene. We also confirm that the selective Pt growth occurs on other kinds of graphene line defects, such as graphene folding structure and cracks (Supplementary Figs 6 and 7).

In terms of chemical reactivity, graphene grain boundaries are believed to have lower reactivity compared with step edges in graphite. For a step edge in HOPG, the chemically active dangling bonds are easily oxidized under exposure to the O_2 counter reactant, leading to nucleation of Pt on those sites³⁸. On the other hand, an ideal graphene grain boundary composes of arrays of pentagon–heptagon carbon rings, where no obvious dangling bond is available^{13,14,40–42}. After 300 ALD cycles, we find that the average size of Pt particles at grain boundaries is around 10 nm (Supplementary Fig. 8), which is significantly smaller than the expected size based on the previous reported growth rate (39 nm with the lateral growth rate of $1.3\text{ \AA}$ per cycle)³⁸. This can be attributed to the nucleation delay effect³⁸, and we estimate that the nucleation delay is around 200 cycles at the grain boundaries from the observed average particle size. Previously, Pt ALD on the step edges of HOPG have shown a nucleation delay of about 100 cycles³⁸. The observed longer nucleation delay at the grain boundaries is an indirect evidence that a grain boundary has somewhat lower chemical reactivity compared with the step edges of HOPG.

DFT calculations of chemical reactivity at grain boundaries. To study the chemical reactivity of grain boundaries in detail, we perform DFT calculations utilizing the PBE/projector-augmented-wave (PAW) functional^{43,44} (see Methods for details). The enhanced reactivity of grain boundaries has been theoretically explored in a number of previous studies^{26–28}, but energetic calculations for binding ALD precursors on graphene grain boundaries are not reported. Detailed energetic calculations can provide a point of comparison on binding different precursors, including various metal and oxide precursors, on graphene grain boundaries. We simulate a graphene grain boundary using a previously reported periodic grain boundary model with a single pentagon–heptagon pair⁴², which is also

Figure 2 | TEM images of Pt growth along grain boundary of CVD graphene. (a) TEM image of suspended CVD graphene after 300 cycles of Pt ALD growth. The distinct growth of Pt along line features is observed. Graphene is supported by an amorphous carbon film surrounding the area of the circle; the enhanced Pt growth seen in this region is occurring on the amorphous carbon TEM support. The small coloured boxes are the field of views for figure b–d. The relative misorientation angle (with respect to grain 1) of graphene grains is shown for each grain. Scale bar, 200 nm. (c) The zoomed-in image at the box c. The upper b and lower c parts of the graphene lattice have a relative rotation of 13°. Scale bar, 0.5 nm.

confirmed by recent atomic-scale experimental observations^{13,14}. We compare DFT-calculated energetics of the surface species formed as a product of the reaction $C_2^* + Pt(CH_3)_3CpCH_3 \rightarrow C-Pt(CH_3)_2CpCH_3^* + C-CH_3^*$, where ‘*’ refers to a surface species and ‘Cp’ to a cyclopentadienyl ring. Notably, it has been previously proposed in the context of Pt ALD on TiO_2 , Al_2O_3 and $SrTiO_3$ that $Pt(CH_3)_3CpCH_3$ reacts on the surfaces by forming $Pt(CH_3)_2CpCH_3$ surface groups⁴⁵.

Three different C_2^* reaction sites located at a strained region, that is, at the pentagon–heptagon pair, are included in the study

(see Fig. 4a) and the results are illustrated in Fig. 4. The PBE/PAW-calculated energetics suggest the Pt precursor chemisorption to a C_2^* unit labelled by B and C (‘B–C’ site) in Fig. 4 to be clearly favoured over the other sites. The high strain associated with the C–C (atoms labelled B and C in Fig. 4) bond shared by the hexagon–heptagon unit is responsible for higher reactivity, in agreement with previous studies^{26,28,46}. The reaction energy originates from the breaking of the Pt–CH₃ bond, the formation of C–Pt and C–CH₃ bonds on the surface and the release of strain in the grain boundary^{26,28} due to buckling of the carbon

Figure 4 | DFT calculations of Pt-precursor chemisorption energetics on the graphene grain boundary. (a) Illustration of a periodic graphene grain boundary model with a heptagon-pentagon unit illustrated in yellow. Reactive carbon sites are labelled as A-D. (b) Top and side views of the surface species formed via chemisorption of $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ on the 'B-C' site. (c) Reaction energies (ΔE) for $\text{C}_2^* + \text{Pt}(\text{CH}_3)_3\text{CpCH}_3 \rightarrow \text{C-Pt}(\text{CH}_3)_2\text{CpCH}_3^* + \text{C-CH}_3^*$ as a function of the active C_2^* site. The reaction energy is defined as the energy difference between the final chemisorbed product and the starting materials (grain boundary slab and gas phase $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$).

framework, as observed in all calculations with the Pt precursor bound at the pentagon-heptagon pair. On the other hand, the reaction product was found to be unstable on the graphene basal plane (see Methods for details), demonstrating the higher reactivity of the graphene grain boundary as compared with the basal plane.

We also perform reaction energy calculations using a cluster model with a hybrid functional, PBE0 for various ALD precursors including $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ and trimethylaluminum (TMA). (See Methods and Supplementary Figs 9 and 10). With $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ reaction energy calculations, we find that the energetic trends from the cluster calculations are in agreement with the periodic calculations, while the absolute values of the reaction energies are lower with the cluster model calculations (Supplementary Fig. 9). We attribute this to the use of different functionals since hybrid functionals, such as PBE0, typically provide more accurate reaction energies than the GGA functionals. The different local strain fields in the two structure models can be also partially responsible for the different calculated reaction energies. The calculated somewhat unfavourable (positive) reaction energies for binding the Pt precursor on graphene grain boundaries are also consistent with the observed longer nucleation delay of around 200 cycles. Moreover, the TMA calculations suggest binding TMA on graphene grain boundaries is more difficult with respect to $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$, and hence TMA may be deposited preferably on more reactive sites on graphene, such as on graphene cracks and edges, compared with grain boundaries (Supplementary Fig. 10). We note that a grain boundary reaction with O_2 reactant, $\text{C}_2^* + \text{O}_2 \rightarrow \text{C-O}^* + \text{C-O}^*$,

Figure 5 | Optical transmittance and sheet resistance measurement.

can be also relevant to the ALD reaction process, and enhanced reactivity with oxygen adatoms at graphene boundaries has been recently reported²⁸.

Optical transmittance and sheet resistance measurements.

Having demonstrated the growth of Pt on graphene grain boundaries by ALD, we now turn to the influence of the deposited Pt on the electronic and optical characteristics of graphene. The monolayer CVD graphene sample has a sheet resistance of $R_s \geq \sim 1 \text{ k}\Omega \text{ sq}^{-1}$, which is still a high resistance for successful application as a conducting transparent electrode⁴⁷. Some origins of the degraded performance of CVD graphene conductance compared with values reported from high-quality monolayer graphene⁴⁸ comes from the 1D defective structures of graphene, which can impede charge transport in graphene and significantly increase the sheet resistance. With respect to this, recent studies have demonstrated that, using a graphene-metal nanowires hybrid structure, very low sheet resistance can be achieved^{49–51}. Similarly, Pt deposition on graphene can boost the electrical conduction since the Pt metal allows for an extra conduction channel. Moreover, since Pt ALD can leave most of the graphene area free of Pt deposition, the obtained graphene-Pt hybrid structure will be able to maintain high transmittance at optical light frequency.

We measure the optical transmittance and conductivity of graphene-Pt hybrid structures as a function of Pt deposition. The pristine graphene samples shows the flat optical transmittance with $T = 97.7\%$ at 550 nm wavelength, which is consistent with the result from a monolayer graphene sample¹² (Fig. 5a). Figure 5a also shows that the graphene samples with 500 and 1,000 ALD cycles exhibit transmittance around 90% and 60%, respectively. We find that the Pt deposition on CVD graphene has some variation; the samples with 500 and 1,000 ALD cycles have $T = 91 \pm 4\%$ and $61 \pm 11\%$, respectively. We attribute this to the batch-to-batch variation in graphene defect density and the degree of surface cleanliness. We also find that the drop in optical transmittance is highly nonlinear to the number of ALD cycles; the formation of Pt islands, as we observed in SEM and TEM images, results in a nonlinear increase in Pt deposition area with respect to the number of ALD cycles.

The conductivity of the graphene-Pt structure is also measured. We obtain the sheet resistance of pristine graphene samples transferred to a glass slide at around $1 \text{ k}\Omega \text{ sq}^{-1}$ in ambient conditions. As the Pt deposition proceeds, the graphene sheet resistance starts to decrease and reaches $\sim 230 \Omega \text{ sq}^{-1}$ at

$T=75\%$ with 1,000 ALD cycles (Fig. 5b). For samples with 500 ALD cycles ($T\sim 90\%$), the conductivity improvement is not significant compared with graphene samples without Pt deposition. Although Pt particles are deposited at the grain boundaries adapting Pt nanowire morphology with 500 ALD cycles, poor inter-particle connectivity and particle-graphene interface may limit the expected conductivity improvement by Pt deposition (Figs 1 and 2).

H₂-sensing experiments with Pt ALD samples. Graphene and carbon nanotubes, especially coupled with other metal and semiconducting materials, have been invested for gas-sensing applications^{6,7,52–55}. With Pt ALD graphene hybrid structures, we perform hydrogen gas-sensing experiments. Functionalization of line defects can allow enhanced response for sensing applications⁵⁵ because this method selectively manipulates various linear defects of CVD graphene, which are the most sensitive sites related to its charge transport properties^{14,15}. In this respect, Pt ALD on graphene can yield a superior platform for sensing applications, allowing the selective functionalization

of graphene defect sites together with the nanowire morphology of deposited Pt.

To assess the effect of selective functionalization of graphene defects, we compare Pt-deposited graphene samples prepared by ALD and e-beam evaporation processes. E-beam evaporation is a physical deposition process, and metal film forms via physisorption on graphene. With the limited mobility of Pt atoms during deposition, Pt islands are quite uniformly located even on the basal plane, regardless of defect locations (Supplementary Figs 11 and 12).

We perform gas-sensing experiments with different Pt thicknesses, since the gas-sensing performance can be influenced by the coverage of Pt. Figure 6a shows the normalized resistance changes of various Pt-graphene samples responding to 0.5% concentrated H₂ in N₂ gas. With the exposure to hydrogen gas (20 min), we observe a resistance increase for all the Pt-deposited graphene samples. The observed resistance increase is consistent with previous reports^{53,56–59}. The mechanism of hydrogen gas sensing is mainly ascribed to the change of doping levels of graphene. Previous investigations have found that the hydrogen molecules dissociate into atomic hydrogen on a Pt surface and the resulting atomic hydrogen lowers the work function of Pt. This in

Figure 6 | H₂-sensing experiments with Pt ALD samples. (a) The normalized resistance changes of Pt-deposited graphene samples responding to 0.5% concentration of H₂ gas. Pt-deposited graphene samples by ALD and e-beam evaporation with various thicknesses are compared. (b) The normalized resistance changes of an ALD sample (1,000 cycles) responding to ultra-low H₂ concentration (2 p.p.m.). (c) The normalized resistance changes of sample with 1,000 ALD cycles responding to various H₂ concentrations. Note that the response to 2 p.p.m., which is shown in b, is also plotted for comparison. (d) Log-scale plot of the normalized change of resistance (after 20 min of H₂ exposure) and the initial rate of normalized resistance change as a function of H₂ concentration.

turn causes the electron transfer from Pt to graphene and reduces the p-doping levels of graphene, resulting in the increase of the resistance^{53,56–59}.

The sample prepared by e-beam evaporation shows an optimal thickness for gas-sensing response⁶⁰. This is related to the coverage of metals on the graphene surface. Ideally, higher Pt coverage on graphene allows for a greater amount of reaction. However, as thicker Pt films are deposited, the Pt metal will eventually form a separate metallic conduction path, which is not sensitive to hydrogen exposure and therefore reduces the sensing performance. In our case, graphene samples on a regular glass slide show an optimal Pt thickness of 0.5 nm for the gas-sensing application (Fig. 6a). Pt (0.5 nm) deposited on graphene shows a normalized response change of around 50% after 20 min of exposure to 0.5% hydrogen gas. With a higher deposition of Pt, 3 nm, the sheet resistance of graphene samples are significantly reduced from $\sim 1 \text{ k}\Omega \text{ sq}^{-1}$ to $\sim 240 \Omega \text{ sq}^{-1}$ (Supplementary Table 2) and the metallic conduction path from the Pt film is dominant. Therefore, the normalized resistance change to hydrogen exposure shows a significantly reduced response.

Compared with the best-performing samples by e-beam evaporation (0.5 nm Pt on graphene), the Pt-graphene sample prepared by ALD (1,000 cycles) clearly shows a better gas-sensing performance. We observe that the 1,000 Pt ALD cycle sample shows a normalized resistance change around 100% with 0.5% hydrogen gas exposure. Moreover, the response to hydrogen gas shows a much faster response compared with evaporated samples, as shown in Fig. 6a. We study the performance of 1,000 Pt ALD cycle samples in further detail. We measure the sensing response with the 1,000 Pt ALD cycle sample to an ultra-low concentration of H_2 gas of 2 p.p.m. As shown in Fig. 6b, we clearly observe a resistance change upon exposure to 2 p.p.m. hydrogen gas. Figure 6c shows the normalized resistance changes of the same sample responding to various hydrogen concentrations. The normalized resistance change after 20 min of hydrogen exposure shows a clear concentration dependence as shown in Fig. 6d. We also plot the initial rate of normalized resistance change as another sensing parameter⁶¹, because the resistance of the samples shows the non-saturating response even after 20 min of exposure for low concentration. Both of the resistance change and the rate of resistance change display very similar concentration-dependent responses. The responses also start to deviate from a straight line, showing saturation above around 500 p.p.m. of hydrogen concentrations.

Discussion

We attribute the observed enhanced gas-sensing performance of ALD samples to two main mechanisms. First, the Pt decoration adapting nanowire shape at the grain boundaries by ALD can provide better functionalization geometry for enhanced electrical response, compared with isolated particle decorations by e-beam evaporation. With Pt nanowires at the grain boundaries, a conduction path between electrodes inevitably goes through Pt-functionalized regions, which are the area of resistance increase via local graphene doping changes^{53,59} or carrier depletion⁵⁵ upon gas exposure. On the other hand, with isolated particle decorations, one can find a conduction pathway, which goes through non-affected regions (Supplementary Fig. 13). If we assume an extreme case where the local resistance increase is infinite by carrier depletion⁵⁵, the conduction pathway will be totally blocked with linear functionalization while the conduction is still possible with point decoration; the effect of resistance change is bigger for linear functionalization. A simple resistance model also predicts the overall sample resistance increase, which scales linearly with a

local resistance increase for the linear functionalization case, whereas the overall resistance rises sub-linearly for the point functionalization. Therefore, the resistance increase will have an enhanced effect in the case of linear decoration with comparable Pt decoration coverage (Supplementary Fig. 13). As a second mechanism for the enhanced sensing response, the interaction between graphene defect sites and dissociated atomic hydrogen may also play an important role, as discussed in carbon nanotube defect functionalization and related sensing measurements⁵⁵.

In conclusion, we demonstrate selective Pt growth at graphene defect sites via ALD. Through direct TEM investigation, we clearly show that Pt predominantly grows at graphene's line defect sites, such as grain boundaries. Since ALD allows for the selective growth of materials on defects of CVD graphene, this method can be used to visualize the locations of graphene defects⁶² and obtain important information on graphene samples, such as grain size of the graphene sample⁶³. We demonstrate that the metal-graphene hybrid structure obtained by ALD can perform as a high-performance hydrogen gas sensor owing to the unique selective functionalization of graphene line defects. Moreover, the metal deposition by ALD is not limited to Pt. The deposition of metals with higher electrical conductivity, such as Ag and Au, would also aid in obtaining lower sheet resistance for transparent conducting electrode applications and give other functionality for sensing and energy storage applications⁷.

Methods

Graphene sample preparation. Graphene was synthesized by CVD on a 25- μm -thick copper foil (99.8% Alfa Aesar, Ward Hill, MA, USA)⁹. In brief, the copper foil was inserted into a quartz tube and heated to 1,040 °C with flowing 10 s.c.c.m. H_2 at 100 mTorr. After annealing for 1 h, the gas mixture of 25 s.c.c.m. CH_4 and 5 s.c.c.m. H_2 at 450 mTorr was introduced for 20 min to synthesize graphene. Finally, fast cool to room temperature with flowing 25 s.c.c.m. CH_4 and 5 s.c.c.m. H_2 was performed.

Graphene transfer to glass slides. For SEM, Raman spectroscopy, optical transmittance and sheet resistance measurement characterization, graphene was transferred to glass slides with PMMA support⁹. A PMMA solution (Sigma-Aldrich product no. 182265, dissolved in chlorobenzene with a concentration of 46 mg ml^{-1}) was spin-coated on the surface of as-grown graphene on Cu foil at the speed of 2,000 r.p.m. for 1 min. The sample was left in air for 1 day to allow the solvent to evaporate thoroughly. O_2 plasma was then applied to remove the graphene layer on the other side of the Cu foil. Then the sample was placed into a solution of sodium persulphate ($\text{Na}_2\text{S}_2\text{O}_8$, a concentration of 0.1 g in 1 ml of water) to etch the underlying copper foil and is then rinsed with deionized water. The PMMA/graphene films were picked up by glass slides and left for 24 h to obtain completely dry samples. The PMMA film was removed by soaking in acetone for 24 h and then rinsed with isopropyl alcohol (IPA) followed by blow drying. Finally, annealing samples with H_2 (20%) and Ar (80%) environment (with total pressure ~ 1 Torr) at 360 °C for 2 h was performed to remove residual PMMA and obtain a cleaner graphene surface.

Graphene TEM grid preparation. For TEM characterization, graphene was transferred to Quantifoil holey carbon TEM grids (SPI Supplies, 300 meshes, 2 μm hole size) using a direct transfer method^{13,64}. We placed the TEM grid onto a graphene-covered copper foil with the carbon film side facing the graphene. Then a small amount of IPA was dropped onto the sample and air-dried. Additional flattening (prior to the IPA step) of the copper foil or TEM grid by sandwiching between glass slides ensures better adhesion. Finally, the sample was placed into a solution of sodium persulphate ($\text{Na}_2\text{S}_2\text{O}_8$, a concentration of 0.1 g in 1 ml of water) to etch the underlying copper foil and is then rinsed with deionized water.

Atomic layer deposition of Pt. Pt was deposited in a custom-designed warm-wall ALD reactor controlled by LabVIEW software using a metalorganic Pt precursor (methylcyclopentadienyltrimethyl-platinum) and air counter-reactant. The graphene surface was pulsed with precursor and counter-reactant for 2 s (50 and 500 mTorr, respectively) during each step, and the chamber was purged for 8 s between pulses. The substrate temperature was fixed at 300 °C. More information on the chamber apparatus and deposition conditions can be found elsewhere³⁸.

Aberration-corrected TEM imaging. TEM imaging was performed at 80 kV using a FEI Titan equipped with a spherical aberration (C_s) corrector in the

image-forming (objective) lens and a monochromator. The C_s coefficient was set to approximately $-10\ \mu\text{m}$. The images were acquired using an Ultrascan 1000 CCD camera.

Characterization. SEM images were acquired with a FEI XL30 Sirion SEM with a field emission gun source, operated at 5 kV. Extra TEM imaging and energy-dispersive X-ray measurement were performed with a FEI Tecnai F20 operated at 200 kV. Raman spectra were measured using a WiTech confocal Raman microscope, which is equipped with a piezo scanner and an intensity-tunable 532 nm NiYAG laser. The optical transmittance measurement was performed with an Agilent Cary 6000i UV/Vis/NIR spectrometer.

Conductivity measurement and hydrogen gas-sensing experiment. Graphene sheet resistance measurement was performed by a four-probe measurement (parallel Au electrodes on graphene) with a Keithley 4200-SCS. H_2 gas-sensing experiment was performed with a home-built measurement setup. The H_2 concentration was controlled by mass flow controllers and the four-probe resistance of samples was recorded (Supplementary Fig. 14).

Computational details. The DFT calculations were performed using the Vienna *Ab initio* Simulation Program (VASP)^{43,44} and the PAW method. A periodic grain boundary model⁴², corresponding to a (1,0) dislocation, with a unit cell composition of C_{292} was utilized. The periodic structural relaxations were performed using the GGA functional PBE⁶⁵ with the PAW potentials implemented in VASP, the conjugate gradient algorithm (IBRION = 2 in VASP input), and Γ point k-sampling. Default accuracy parameters for the FFT grid and real space projectors (PREC = NORMAL in VASP input) were adopted. A vacuum thickness of 20 Å was utilized to avoid interactions between graphene and its periodic images.

Supplementary calculations were performed using the PBE0 (refs 65,66) functional with the standard split-valence + polarization (def-SVP)^{67,68} basis set and without symmetry constraints. Quasirelativistic effective core potentials were utilized for 60 core electrons of Pt⁶⁹. A $\text{C}_{50}\text{H}_{16}$ cluster with H-terminated edges and a diameter of about 1.5 nm was utilized to represent the local atomic structure of the graphene grain boundary with pentagon–heptagon pairs. The graphene basal plane was simulated by a $\text{C}_{42}\text{H}_{16}$ cluster with H-terminated edges. Full structural optimizations without symmetry constrained by the PBE0 hybrid functional were performed on the pristine graphene grain boundary cluster, the $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ molecule and the systems with $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ chemisorbed on the grain boundary cluster. The computed total energies were used in the determination of the reaction energies (Supplementary Fig. 9). In the investigation of $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ chemisorption on the C_2 reaction sites on the graphene grain boundary, both structural alternatives of the product were considered and the energetically favoured one was reported. All cluster calculations were performed with Gaussian09 software package⁷⁰.

For comparison with the results for binding $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ on graphene grain boundaries, we performed analogous cluster calculations for TMA, which is a typical ALD precursor for depositing alumina. The results are summarized in Supplementary Fig. 10, where the sites B-C, C-C and C-D are energetically practically equal for TMA chemisorption. The stabilization of these sites with respect to the A-B site is due to coordination of the Al atom to two neighbouring C atoms with the Al atom being located above the C–C bond. In comparison with the $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ calculations, the most favourable reaction energies for TMA are around $15\ \text{kcal mol}^{-1}$, whereas the calculated reaction energy for binding $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ on the B-C site is about $8\ \text{kcal mol}^{-1}$. Thus, the results suggest binding TMA on graphene grain boundaries is more difficult with respect to $\text{Pt}(\text{CH}_3)_3\text{CpCH}_3$ and, hence, TMA might only bind on more reactive sites on graphene, such as on graphene cracks and graphene edges.

Acknowledgements

We thank Tae Hoon Lee and John To for valuable discussion and technical assistance. We also thank Professor Oleg Yazyev for sharing a periodic graphene grain boundary model. This work was supported by Stanford Global Climate and Energy Program. Pt ALD was supported by the US Department of Energy, Office of Science, Basic Energy Sciences, under Award #DE-SC0004782. J.T.T. gratefully acknowledges the Academy of Finland (Grant 256800/2012) and the Finnish Cultural Foundation for financial support.

Author contributions

K.K. and H.-B.-R.L. contributed to this work equally. K.K., H.-B.-R.L., S.F.B. and Z.B. designed the experiments. H.-B.-R.L. and R.W.J. carried out Pt deposition by ALD on graphene samples. K.K. performed sample fabrication, characterizations and gas-sensing experiments. N.L., M.-G.K., C.P. and C.A. helped with sample fabrication and characterizations. J.T.T. performed theoretical calculations. K.K., H.-B.-R.L., J.T.T. and Z.B. co-wrote the paper. All authors discussed the results and commented on the manuscript.
