High-performance flexible perovskite solar cells exploiting Zn_2SnO_4 prepared in solution below 100°C

Seong Sik Shin^{1,2,3,*}, Woon Seok Yang^{1,*}, Jun Hong Noh¹, Jae Ho Suk^{2,3}, Nam Joong Jeon¹, Jong Hoon Park^{1,2}, Ju Seong Kim^{2,3}, Won Mo Seong^{2,3} & Sang Il Seok^{1,4}

Fabricating inorganic-organic hybrid perovskite solar cells (PSCs) on plastic substrates broadens their scope for implementation in real systems by imparting portability, conformability and allowing high-throughput production, which is necessary for lowering costs. Here we report a new route to prepare highly dispersed Zn_2SnO_4 (ZSO) nanoparticles at low-temperature ($<100^\circ\text{C}$) for the development of high-performance flexible PSCs. The introduction of the ZSO film significantly improves transmittance of flexible polyethylene naphthalate/indium-doped tin oxide (PEN/ITO)-coated substrate from ~ 75 to $\sim 90\%$ over the entire range of wavelengths. The best performing flexible PSC, based on the ZSO and $\text{CH}_3\text{NH}_3\text{PbI}_3$ layer, exhibits steady-state power conversion efficiency (PCE) of 14.85% under AM 1.5G $100\text{ mW}\cdot\text{cm}^{-2}$ illumination. This renders ZSO a promising candidate as electron-conducting electrode for the highly efficient flexible PSC applications.

Since the first application of organic–inorganic perovskite materials into solar cells in 2009 (ref. 1), tremendous progress has been made in this field. Recently, we have demonstrated the confirmed efficiencies exceeding 18% for small-sized devices². Highly efficient perovskite solar cells (PSCs) with ignorable hysteresis mainly use mesoporous (mp)-TiO₂ as the electron acceptor and hole barrier layer^{3–5}, although several materials, including Al₂O₃ (ref. 6), ZrO₂ (ref. 7) and SrTiO₃ (ref. 8) and so on, have been applied as electrodes. The drawback with mp-TiO₂ is that a high-temperature process (> 400 °C) is required, which prevents the use of low-cost, lightweight and flexible plastic substrates as they are unstable at high temperatures. Hence, low-temperature processable metal oxides are required for the construction of industrial printing processes with high-throughput production lines, in order to achieve the associated potential reduction in manufacturing costs^{9,10}. In addition, the use of plastic substrates can enable portable, conformable and lightweight solar cells linked with consumer electronics. However, the PCEs of flexible solar cells fabricated on plastic substrates have generally been very low in comparison with those of PSCs fabricated on rigid substrates.

The first PSC using low-temperature processed metal oxide on a flexible substrate was demonstrated with a very low PCE of 2.62% by Mathews's group using ZnO nanorods¹¹. More recently, PCE of 10.2% was obtained using ZnO nanoparticles (NPs) deposited on polymer substrates, whereas low-temperature processed mp-TiO₂ delivered solar cells with 8.4% efficiency¹². Most recently, Jung *et al.*¹³ reported an efficient flexible PSC exhibiting champion PCE of 12.2% using a metal oxide electron transport layer; however, they used a compact TiO_x layer, deposited by atomic layer deposition, which is not solution processable. This state-of-the-art flexible PSC has provoked our interest in the use of other solution-processable metal oxide to further improve the performance. However, the synthesis of crystalline metal oxide NPs in solution requires mostly high temperature and high pressure. Furthermore, it will be important to prepare the particles which have capabilities to form a uniform and dense layer without additional steps, in particular at elevated temperature.

Zn₂SnO₄ (ZSO) is well known as a transport-conducting oxide for use in optoelectronic applications, due to its acceptable electrical and optical properties¹². It is an n-type semiconductor with a small electron effective mass of 0.23 *m_e* and a high-electron Hall mobility of 10–30 cm² Vs^{−1} (ref. 14). In addition, it has a wide optical band gap of 3.8 eV and a relatively low refractive index of ~2.0 in the visible spectrum^{15,16}. Furthermore, the conduction band edge position that is similar to that of TiO₂ and ZnO makes it an excellent photoelectrode in emerging solar cell technologies, such as PSC, dye sensitized solar cell (DSSC) and organic photovoltaic (OPV)^{17–19}. Finally, the most attractive attribute of crystalline ZSO is its chemical stability with respect to acid/base solution and polar organic solvents, for solution

processing^{20,21}. However, the ZSO ternary system is not easy to synthesize as highly dispersed NPs, and requires rather high temperatures (> 200 °C) to crystallize, compared with binary oxide systems (that is, TiO₂, ZnO and SnO₂) because both Zn and Sn ions must be regulated during a synthetic reaction. Generally, the synthesis temperature of ZSO is considerably influenced by the type of zinc precursor complex^{19,22}. In the conventional route, ZSO NPs are synthesized with a strong base, such as NaOH, via ZnSn(OH)₆ intermediate phase. However, a high reaction temperature (> 200 °C) is required for the transformation of ZnSn(OH)₆ into crystalline ZSO²³. Several groups have attempted to reduce the reaction temperature by controlling the Zn complex-precursors using -amine and -carbonate mineralizers, resulting in the formation of Zn(OH)₄^{2−} and Zn₅(CO₃)₂(OH)₆ (refs 19,22,24). However, high temperatures (> 150 °C) are still required for the dissociation/condensation process with Sn(OH)₆^{2−}, inducing irregular shaped and agglomerated ZSO NPs.

Here, we report flexible PSCs comprised of a polyethylene naphthalate/indium-doped tin oxide (PEN/ITO) substrate, a low-temperature solution-processed ZSO layer, a CH₃NH₃PbI₃ perovskite layer, a poly(triarylamine) hole conductor layer and Au as the electrode. Notably, the presence of the ZSO layer allowed superior transmittance in the visible regions, compared with bare flexible PEN/ITO substrate. This was due to an anti-reflection effect, attributable to the low refractive index of ~1.37. A high PCE, exceeding 15%, with high-quantum efficiency was achieved. To the best of our knowledge, this PCE is the highest performance reported for flexible PSCs using metal oxide electrodes^{11,13,25}.

Results

Synthesis of ZSO NPs via Zn-hydrazine complex precursor.

The strategy for synthesizing ZSO NPs below 100 °C is schematically depicted in Fig. 1. To synthesize highly dispersed, low-temperature ZSO NPs, the chemical reactions were carried out at 90 °C for 12 h, with various molar N₂H₄/Zn ratios. Figure 2a shows the X-ray diffraction (XRD) patterns of powders synthesized at 90 °C for 12 h, as a function of the different molar N₂H₄/Zn ratios (2, 8 and 24). At a low N₂H₄ concentration (N₂H₄/Zn = 2), the only pure SnO₂ phase is observed, whereas a pure ZSO phase with an inverse spinel structure (JCPDS 24-1470) is obtained at N₂H₄/Zn ratio = 8. However, an excessive of N₂H₄, that is, N₂H₄/Zn = 24, produces highly crystalline ZnSn(OH)₆ as a secondary phase besides ZSO. It is well known that N₂H₄ can act, not only as a complexing agent but also as an OH supplier by a dissociation reaction during the reaction process^{26,27}. Therefore, the variance in OH concentration caused by N₂H₄ can influence the formation of crystalline phases (SnO₂, ZSO and ZnSn(OH)₆). Figure 2b shows XRD patterns of the synthesized powders with different reaction temperature, from 80 to 95 °C, with

Figure 1 | Synthetic procedure for ZSO. Schematic illustration for the formation of highly dispersed ZSO NPs with a reaction temperature below 100 °C.

Figure 2 | XRD and Fourier transform infrared (FT-IR) of samples obtained with various reaction conditions. Powder X-ray diffractograms (CuK α radiation) of (a) different $\text{N}_2\text{H}_4/\text{Zn}$ ratios (90 °C, 12 h), (b) different reaction temperatures ($\text{N}_2\text{H}_4/\text{Zn} = 8$, 12 h) and (c) different reaction times (90 °C, $\text{N}_2\text{H}_4/\text{Zn} = 8$). (d) FT-IR spectra of samples synthesized at different reaction times (90 °C, $\text{N}_2\text{H}_4/\text{Zn} = 8$). Unindexable peaks are denoted as (+).

$\text{N}_2\text{H}_4/\text{Zn} = 8$. Unindexable peaks, denoted by '+', are observed with the ZSO phase at 80 and 85 °C, whereas all peaks are indexed by the ZSO phase at 90 and 95 °C. The unindexable peaks (to be discussed later) are related to new Zn–N–H–OH complexes in this process, indicating that a temperature below 90 °C is insufficient to drive the dissociation/condensation reaction of such complex precursor for the formation of ZSO crystal. Therefore, N_2H_4 concentration and reaction temperature are the key factors for synthesizing pure crystalline ZSO at a temperature below 100 °C. To understand the formation mechanism of ZSO crystals by N_2H_4 complexing below 100 °C, a time-dependent experiment was performed under certain conditions ($\text{N}_2\text{H}_4/\text{Zn} = 8$ and 90 °C). Figure 2c shows the XRD patterns of powder prepared at different reaction times. According to the XRD traces, before heating (0 h), peaks (●) indexed for $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ (JCPDS 72-0620) are dominant compared with the unindexable peaks (+). However, the unindexable peaks predominate over the peaks corresponding to $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ after 1 h of heating. The peaks corresponding to $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ gradually disappear, whereas unindexable peaks, including the main peak at 10.7°, further develop with an increase in the reaction time until 3 h, implying the transformation of $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ into new complex. After 5 h,

most of the peaks based on the new complex disappear and pure ZSO crystal phases are observed with complete decomposition of the new complex. Also, the intensity of the ZSO peaks increase with an increase in the reaction time (12, 18 and 24 h), suggesting an increase in particle size (Supplementary Fig. 1). Our process was summarized in a flow chart (Supplementary Fig. 2). Based on these results, it can be concluded that the formation of new complex-precursors has a decisive effect on the low-temperature formation of ZSO crystals.

Fourier transform infrared analysis was performed to reveal the possible composition of the new complex-precursors and to further study the formation mechanism (Fig. 2d). At 0 h, the characteristic peaks of $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$, such as N–H stretching (3,188 and 3,285 cm^{-1}), NH_2 bending (1,571 and 1,607 cm^{-1}), NH_2 twisting (1,168 cm^{-1}) vibration and N–N stretching (976 cm^{-1}) vibration are observed and are accordant with the reported values²⁸. In particular, the peak at 976 cm^{-1} appears when the N_2H_4 coordinates two metal ions in a bidentate bridging mode, which is strong evidence for the formation of a metal hydrazine complex²⁹. Importantly, with an increase in reaction time up to 3 h at 90 °C, the N–N stretching (976 cm^{-1}), the NH_2 bending (1,571 and 1,607 cm^{-1}) and the NH_2 twisting (1,168 cm^{-1}) peaks gradually disappear. Conversely, the N–H

stretching peaks at 3,188 and 3,285 cm^{-1} remain, but with small shift, and the peaks at 3,418 and 3,516 cm^{-1} are much better pronounced. The peak at 3,418 cm^{-1} is due to stretching of the OH linked to the matrix, and the peak at 3,516 cm^{-1} is due to coordinated/adsorbed water molecules, respectively³⁰. These results may imply decomposition of the zinc bishydrazine complex into a zinc ammine complex that includes OH^- ions (Zn-N-H-OH). In addition, by energy dispersive spectroscopy analysis, we observe the reduction and removal of Cl^- with the increase in reaction time from 0 to 3 h (Supplementary Fig. 3). These results indicate that new Zn-N-H-OH complex-phases are formed during the reaction, by decomposition of N_2H_4 , removal of Cl^- ions, and incorporation of OH^- ions from initial $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ complex. As the reaction progresses over 6 h, all of the characteristic peaks for the Zn-N-H-OH complex disappear, suggesting the formation of a crystalline ZSO, which is in accordance with the XRD results.

Based on the series of experiments described above, we propose a possible formation mechanism, as illustrated in Fig. 3a, to rationalize the formation of ZSO NPs at temperatures below 100 °C. When the hydrazine concentration is low ((i) route: acidic condition), H_2SnO_3 is produced due to the strong hydrolysis effect of Sn^{4+} , which can lead to the formation of SnO_2 , whereas Zn^{2+} ions remain in the solution and are washed away after the reaction²³. On the other hand, an appropriate concentration of hydrazine ((ii) route: mild alkaline condition) prevents the hydrolysis reaction of Sn^{4+} , and favours the formation of $\text{Sn}(\text{OH})_6^{2-}$ rather than H_2SnO_3 (ref. 21), whereas the Zn^{2+} ion forms a $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ complex with hydrazine^{31,32}. In metal-hydrazine systems, the metal/hydrazine ratio is an important factor for determining the composition of the hydrazine complex such as $\text{M}(\text{N}_2\text{H}_4)_x\text{Cl}_2$, $\text{M}(\text{N}_2\text{H}_4)_2\text{XCl}_2$ and $\text{M}(\text{NH}_3)_x\text{Cl}_2$ (refs 33,34). In our case ($\text{N}_2\text{H}_4/\text{Zn}=8$), $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ is the dominant form initially (at 0 h), as it is more stable than other compositions. As the reaction progresses, the zinc ammine hydroxo complex, Zn-N-H-OH , is formed by the reaction of $\text{Zn}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ with excess N_2H_4 , and a continuous supply of OH^- (ref. 35). Compared with other metal complexes, the metal ammine hydroxo complex requires a relatively low temperature

(<100 °C) for the formation of the crystalline metal oxide. This is due to the low-energy kinetics of metal-ammine dissociation and the hydroxide condensation/dehydration reaction^{36,37}. Therefore, we believe that Zn-N-H-OH complexes can lead to the formation of crystalline ZSO with $\text{Sn}(\text{OH})_6^{2-}$, even below 100 °C. However, an excess hydrazine ((iii) route: alkaline condition) leads to the formation of $\text{ZnSn}(\text{OH})_6$ as a secondary phase. The increased pH favours the substitution of N-H with OH^- in the Zn-N-H-OH complex, resulting in the partial formation of $\text{Zn}(\text{OH})_4^{2-}$ (ref. 38). In this case, $\text{ZnSn}(\text{OH})_6$ can be produced as a secondary phase, in which the transformation of $\text{ZnSn}(\text{OH})_6$ into ZSO requires a high temperature (>200 °C)²³. As a result, both ZSO and $\text{ZnSn}(\text{OH})_6$ are formed during the 90 °C reaction. From these results and additional detailed experiments, we propose a rough formation map of ZSO, which outlines the effects of variations in temperature and $\text{N}_2\text{H}_4/\text{Zn}$ ratio, for the process below 100 °C (Fig. 3b). As shown in the map, an $\text{N}_2\text{H}_4/\text{Zn}$ ratio in the range of 8–24 at a temperature of around 90 °C, leads to a crystalline ZSO phase without secondary phases, which is the first demonstration of the synthesis of pure ZSO at a low temperature (<100 °C). This mild synthesis condition is comparable to that of binary oxides (TiO_2 or ZnO), and can provide powerful competitiveness as an alternative to binary oxides for various device applications.

Deposition of ZSO thin layers onto substrates. Figure 4a,b shows representative transmission electron microscopy (TEM) images and selected area electron diffraction (SAED) patterns of the ZSO NPs synthesized at 90 °C for 12 h. The TEM image exhibits highly dispersed and defined particles with a narrow size distribution (~11 nm). The formation of uniform and dispersed NPs can be ascribed to the low reaction temperature and the formation of a stable precursor complex with hydrazine³³. In addition, the high-resolution TEM image (inset in Fig. 4a) and the SAED patterns (Fig. 4b) are in agreement with the spinel structure of ZSO deduced from XRD patterns. Moreover, elemental mapping by energy dispersive spectroscopy indicates the homogeneous distribution of Zn and Sn elements in the NPs,

(d) transmittance spectra of ZSO films on fused silica substrate with four coating times (inset: the photograph of ZSO colloidal solution and the resultant ZSO film). (e) The reflective index (n) and the extinction coefficient (k) of low-temperature processed ZSO film.

Figure 5 | Experimental procedure for PSCs. Schematic illustration of the low-temperature process for fabricating flexible device with ZSO NPs.

as presented in Supplementary Fig. 4. For fabrication of high throughput and flexible optoelectronic applications, characterization of the low-temperature, solution-processed ZSO film is required. We deposited ZSO film on fused silica substrates by spin-coating and drying at 100 °C, using the resultant crystalline ZSO colloidal solution. The scanning electron microscopy (SEM) images of the ZSO film are shown in Fig. 4c. The plane image (Fig. 4c above) reveals that the surface exhibits crack-free, uniform morphology, with densely packed NPs (inset in Fig. 4c above). The atomic force microscopy analysis (Supplementary Fig. 5) indicates the resultant ZSO film has a flat surface with a root-mean-square roughness of 2.07 nm. Moreover, the entire substrate surface is uniformly covered by ZSO NPs with a thickness of ~100 nm (Fig. 4c below). Figure 4d shows the optical transmission spectra of a ZSO film on quartz after several coating cycles. The transmittance of ZSO films is comparable to bare fused silica substrates over the entire wavelength region, regardless of their thickness (various coating cycles, Supplementary Fig. 6). The photograph (inset in Fig. 4d) shows that the ZSO film fabricated from the highly dispersed ZSO colloidal solution is highly transparent. The high transparency can be ascribed to the optical properties of the ZSO film. Figure 4e shows the refractive index (n) and extinction coefficient

(k) spectra for ~100-nm-thick ZSO film deposited on a silicon substrate measured using spectroscopic ellipsometry. The refractive index n is significantly small around 1.37 throughout the entire visible range compared with the reported value of 2.0 for ZSO film¹⁶. Because the refractive index for NP film has been reported to be determined by its crystallinity and porosity^{39,40}, the ZSO film prepared from the low-temperature ZSO colloidal solution may possess low refractive index. In addition, the low extinction-coefficient value of nearly 0 in the visible region is in accordance with previously reported one¹⁶. The unique optical properties of the ZSO film such as lower refractive index ($n \sim 1.37$) than SiO_2 glass ($n \sim 1.5$), wide band gap, and low-extinction coefficient (k) are causes of improved transmittance of the fused silica substrate, even after coating with the ZSO film. These results reveal that the low-temperature-synthesized ZSO NPs can facilitate the formation of highly transparent and uniform film on substrate without additional treatment.

Fabrication of ZSO-based flexible PSCs. To demonstrate its viability for high throughput and flexible optoelectronic applications, ZSO film was employed, after four coating cycles, as an electron transport layer over PEN/ITO substrate. The ZSO film

on ITO substrate, in common with those seen on quartz, has flat (root-mean-square: 3.76 nm) and uniform morphology with densely packed NPs (Supplementary Fig. 7). Figure 5 shows a series of processing steps from ZSO NPs formation to flexible solar cell fabrication. All steps require very simple techniques and low processing temperature below 100 °C. This is the first demonstration of low-temperature process for a ternary oxide electron transport layer to apply in PSCs, which can possibly provide an alternative to conventional TiO_2 - or ZnO -based PSCs. Figure 6a,b presents a colour-enhanced cross-sectional SEM image of the device architecture fabricated in this study and the

corresponding energy level diagram of the device based on reported values^{17,41}, respectively. As shown in Fig. 6a, two uniform layers, ZSO layer and a perovskite layer, are observed; the flat and homogeneous ZSO film with a thickness of 110 ± 10 nm can lead to uniform perovskite film on the ITO/ZSO substrate by using pre-reported solvent-engineering technique³. Furthermore, the plane-view SEM image (Supplementary Fig. 8) showed that the perovskite layer on ZSO was deposited in dense and uniformly spread film with fine-grained morphology, which is similar with our previous report³. The fabricated flexible PSC is shown in the photograph in Fig. 6a.

Figure 6 | Structure and performance of ZSO-based flexible perovskite solar cell. (a) Cross-sectional SEM image and photograph of the ZSO-based flexible perovskite solar cell (scale bar, 500 nm). (b) Energy levels of the materials used in this study. (c) Photocurrent density-voltage (J - V) curve measured by reverse scan with 10 mV voltage steps and 40 ms delay times under AM 1.5 G illumination. (d) EQE spectrum of the ZSO-based flexible perovskite solar cell. (e) Transmittance and reflectance spectra of PEN/ITO/ZSO, PEN/ITO/ TiO_2 and PEN/ITO substrate. A dense TiO_2 film was fabricated by TiO_2 NPs obtained from a non-hydrolytic sol gel route⁹ (Supplementary Fig. 12).

Figure 6b reveals that the energy level of ZSO is similar to that of TiO_2 , implying that it has an identical working mechanism as a TiO_2 -based PSCs. Figure 6c shows the photocurrent density–voltage (J - V) curve of the ZSO-based flexible PSC under simulated solar illumination (100 mW cm^{-2} air mass (AM) 1.5G). The J - V curve exhibits a short circuit current density (J_{sc}) of 21.6 mA cm^{-2} , an open circuit voltage (V_{oc}) of 1.05 V , and fill factor (FF) of 0.67 , resulting in PCE (η) of 15.3% with steady-state PCE of 14.85% , which is comparable to the performance of ZSO-based PSC, prepared on ITO glass (Supplementary Fig. 9 and Supplementary Table 1). ZSO-based PSC shows the hysteresis in the J - V curves measured with reverse and forward scan (Supplementary Fig. 10 and Supplementary Table 2), although it is smaller than those of our TiO_2 -based planar device reported by us³. However, in contrast to TiO_2 -based planar PSCs reported by other groups⁴, the stabilized photocurrent density and PCE obtained from ZSO NPs-based planar PSC approaches the value measured by reverse mode (Supplementary Fig. 10). This result is consistent with that of mesosuperstructured solar cells⁴. We repeated the fabrication procedure to obtain a reliable and reproducible result. As can be seen in the histogram for the photovoltaic parameters collected from 60 independent devices (Supplementary Fig. 11 and Supplementary Table 3), around 40% of the cells show PCE over 13% with the average PCE of 13.7% . In particular, the average J_{sc} and V_{oc} exceed 20 mA cm^{-2} and 1 V , respectively, which is much greater than other flexible PSCs based on $\text{TiO}_2/\text{ZnO}/\text{PEDOT:PSS}$. Furthermore, the flexible device shows a very broad external quantum efficiency (EQE) plateau over 80% between 460 and 755 nm , as shown in Fig. 6d. Integrating the product of the AM 1.5 G photon flux with the EQE spectrum yield a predicted J_{sc} of 21.2 mA cm^{-2} , which agrees well with the measured value of 21.6 mA cm^{-2} . This high EQE corresponding to a high J_{sc} for ZSO-based PSCs reveals that the ZSO film prepared at low-temperature produces excellent electron collecting and light harvesting ability within the device. The high performance ($\geq 15\%$) of flexible PSCs is first demonstrated using the newly designed, solution-processed ZSO film, which is superior to the reported TiO_2 - and ZnO -based flexible PSCs^{13,25}. The higher charge collecting ability might be due to the higher electron mobility of ZSO in nature than conventional TiO_2 (refs 15,18). In addition to the high mobility of ZSO, the lower refractive index ($n \sim 1.4$) of the ZSO film than TiO_2 film ($n \sim 2.5$) leads to further light harvesting gain due to the anti-reflectance effect between ITO ($n \sim 2.0$) and ZSO or TiO_2 layers. Figure 6e presents the transmittance and diffused reflectance spectra for bare PEN/ITO, PEN/ITO/ TiO_2 and PEN/ITO/ZSO substrate. Introduction of the ZSO film brings significant reduction of the reflectance over the entire wavelength region, resulting in improvement of transmittance from ~ 75 to $\sim 90\%$. As ITO on PEN film has a lower refractive index than the ITO film on glass due to lower crystallinity by low-temperature processing, reflectance loss between ITO and TiO_2 for flexible substrate can be larger than that of glass substrate⁴². The ZSO film overcomes the poor transmittance caused by the flexible substrate⁴³, which can lead a comparable J_{sc} with that of a device based on glass substrate. As a result, superior electrical/optical properties of ZSO film can improve the J_{sc} for flexible PSCs. In addition, we performed mechanical bending tests over 300 cycles. As shown in Supplementary Fig. 13, the performance of the device retains over 95% of its initial efficiency even after 300 bending cycles.

Discussion

A well-dispersed crystalline ZSO colloidal solution was synthesized by the introduction of a Zn–N–H–OH complex derived

from hydrazine via simple solution process at 90°C . The flat and uniform ZSO films on flexible PEN/ITO substrate were also fabricated by a spin-coating method using the colloidal solution with drying at 100°C . An n-type semiconducting ZSO film with wide band gap (3.8 eV) on flexible substrate has great potential for use in flexible optoelectronic devices. The resultant ZSO film shows a very low refractive index around 1.37 throughout the entire visible range, leading to improved transmittance of PEN/ITO substrate due to anti-reflection. The PSC using the highly transparent PEN/ITO/ZSO substrate showed high-quantum efficiency and a PCE of 15.3% , which is comparable to that of device based on rigid glass. This low-temperature synthetic method can provide a breakthrough for the fabrication of metal-oxide semiconductors on flexible substrate in advanced optoelectronic applications as a technology capable of high performance and large production.

Methods

Synthesis of ZSO NPs. All chemicals for the preparation of NPs were of reagent grade and were used without further purification. ZnCl_2 (12.8 mmol , Aldrich) and $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$ (6.4 mmol , Aldrich) were dissolved in deionized water (160 ml) under vigorous magnetic stirring. $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O}$ (N_2H_4 molar ratio/ $\text{Zn} = 4/1, 8/1, 24/1$) was then added to the reaction solution. White precipitates formed immediately, and this solution, including the precipitate, was heated on a hot plate at 90°C for 12 h . The obtained products were thoroughly washed with deionized water and ethanol and were then dispersed in 2-methoxy ethanol, resulting in a colloidal solution.

Solar cell fabrication. A ZSO thin film was prepared by spin coating the colloidal dispersion of ZSO particles onto ITO-coated glass/PEN substrate at $3,000 \text{ r.p.m.}$ for 30 s , followed by drying on a hot plate at 100°C for 3 min . To control film thickness, the procedure was repeated four times. After baking at 100°C for 1 h in air, the perovskite layer was deposited onto the resulting ZSO film by a consecutive two-step spin coating process at $1,000$ and $5,000 \text{ r.p.m.}$ for 10 and 20 s , respectively, from the mixture solution of methylammonium iodide ($\text{CH}_3\text{NH}_3\text{I}$) and PbI_2 . During the second spin coating step, the film was treated with toluene drop-casting, and then was dried on a hot plate at 100°C for 10 min . The detailed preparation of the $\text{CH}_3\text{NH}_3\text{I}$ has been described in previous work³. A solution of poly(triarylamine) (EM index, $M_n = 17,500 \text{ g mol}^{-1}$, 15 mg in toluene 1.5 ml) was mixed with $15 \mu\text{l}$ of a solution of lithium bistrifluoromethanesulphonimide (170 mg) in acetonitrile (1 ml) and $7.5 \mu\text{l}$ 4-tert-butylpyridine. The resulting solution was spin coated on the $\text{CH}_3\text{NH}_3\text{PbI}_3/\text{ZSO}$ thin film at $3,000 \text{ r.p.m.}$ for 30 s . Finally, an Au counterelectrode was deposited by thermal evaporation.

Characterization. The crystal structure and phase of the materials were characterized using an XRD (New D8 Advance, Bruker) and SAED. The chemical composition of materials was investigated using a Fourier transform infrared spectrometer (Nicolet 6700, Thermo Scientific). The morphologies and microstructures were investigated by field emission scanning electron microscopy (FESEM, SU 70, Hitachi), transmission electron microscopy (TEM, JEM-2,100 F, JEOL) and atomic force microscopy (NanostationII, Surface Imaging Systems). The optical properties of samples were characterized using an ultraviolet–visible spectrophotometer (UV 2,550, Shimadzu). The EQE was measured using a power source (300 W xenon lamp, 66,920, Newport) with a monochromator (Cornerstone 260, Newport) and a multimeter (Keithley 2001). The J - V curves were measured using a solar simulator (Oriel Class A, 91,195 A, Newport) with a source meter (Keithley 2,420) at 100 mW cm^{-2} , AM 1.5 G illumination, and a calibrated Si-reference cell certified by the NREL. The J - V curves were measured by reverse scan (forward bias (1.2 V) $\rightarrow$ short circuit (0 V)) or forward scan (short circuit (0 V) $\rightarrow$ forward bias (1.2 V)). The step voltage and the delay time were fixed at 10 mV and 40 ms , respectively. The J - V curves for all devices were measured by masking the active area with a metal mask 0.096 cm^2 in area. Time-dependent current was measured with a potentiostat (PGSTAT302N, Autolab) under one sun illumination.

Acknowledgements

This research was supported by the Global Research Laboratory (GRL) Program, the Global Frontier R&D Program of the Center for Multiscale Energy System funded by the National Research Foundation in Korea, and by a grant from the KRICT 2020 Program for Future Technology of the Korea Research Institute of Chemical Technology (KRICT), Republic of Korea. S.S.S. thanks Hye-Eun Nam, at Kaywon School of Art and Design for supporting graphic illustration, for her graphical assistance.

Author contribution

S.S.S., W.S.Y. and S.I.S. conceived the experiments, data analysis and interpretation. S.S.S., J.S.K., J.H.P., W.M.S. and J.H.S. carried out the synthesis and characterization of Zn_2SnO_4 nanoparticles. W.S.Y., S.S.S. and N.J.J. performed the fabrication of films and devices, device performance measurements and characterization. N.J.J. and W.S.Y. carried out the synthesis of materials for perovskites. The manuscript was mainly written and revised by S.S.S., J.H.N. and S.I.S. The project was planned, directed and supervised by S.I.S. All authors discussed the results and commented on the manuscript.
