The Volitional Nature of Nicotine Exposure Alters Anandamide and Oleoylethanolamide Levels in the Ventral Tegmental Area

Matthew W Buczynski¹, Ilham Y Polis¹ and Loren H Parsons^{*,1}

Cannabinoid-1 receptors (CB₁) have an important role in nicotine reward and their function is disrupted by chronic nicotine exposure, suggesting nicotine-induced alterations in endocannabinoid (eCB) signaling. However, the effects of nicotine on brain eCB levels have not been rigorously evaluated. Volitional intake of nicotine produces physiological and behavioral effects distinct from forced drug administration, although the mechanisms underlying these effects are not known. This study compared the effects of volitional nicotine self-administration (SA) and forced nicotine exposure (yoked administration (YA)) on levels of eCBs and related neuroactive lipids in the ventral tegmental area (VTA) and other brain regions. Brain lipid levels were indexed both by *in vivo* microdialysis in the VTA and lipid extractions from brain tissues. Nicotine SA, but not YA, reduced baseline VTA dialysate oleoylethanolamide (OEA) levels relative to nicotine-naïve controls, and increased anandamide (AEA) release during nicotine intake. In contrast, all nicotine exposure paradigms increased VTA dialysate 2-arachidonoyl glycerol (2-AG) levels. Thus, nicotine differentially modulates brain lipid (2-AG, AEA, and OEA) signaling, and these modulations are influenced by the volitional nature of the drug exposure. Corresponding bulk tissue analysis failed to identify these lipid changes. Nicotine exposure had no effect on fatty acid amide hydrolase activity in the VTA, suggesting that changes in AEA and OEA signaling result from alterations in their nicotine-induced biosynthesis. Both CB₁ (by AEA and 2-AG) and non-CB₁ (by OEA) targets can alter the excitability and activity of the dopaminergic neurons in the VTA. Collectively, these findings implicate disrupted lipid signaling in the motivational effects of nicotine.

Keywords: nicotine; endocannabinoid; anandamide; 2-arachidonoylglycerol; oleoylethanolamide; ventral tegmental area

INTRODUCTION

Recent preclinical and clinical studies demonstrate an important involvement of cannabinoid-1 receptor (CB₁) in the etiology of nicotine addiction. Several studies have demonstrated nicotine-induced alterations in brain CB₁ receptor expression and function (Gerard *et al*, 2010; Marco *et al*, 2007; Werling *et al*, 2009). Screening of two independent clinical populations revealed that CB₁ gene variants are associated with nicotine dependence (Chen *et al*, 2008) and the CB₁ receptor antagonist Rimonabant (SR141716A) prolonged abstinence rates in smokers expressing motivation to quit (Le Foll *et al*, 2008). SR141716A and the related CB₁ antagonist AM251 reduce nicotine self-administration (SA) by rats (Cohen *et al*, 2002, 2005; Forget *et al*, 2009; Shoaib, 2008), attenuate nicotine-induced increases in nucleus accumbens (NAc) dopamine (DA)

(Cheer *et al*, 2007; Cohen *et al*, 2002; Grieder *et al*, 2012), and reduce reinstatement of nicotine-seeking behavior in animal models of relapse (Forget *et al*, 2009). Collectively, these findings provide strong evidence for a CB₁ receptor involvement in the motivational effects produced by nicotine, and imply a role for endocannabinoid (eCB) signaling in this process.

To date, only one study has directly evaluated brain eCB content following nicotine exposure. Gonzalez and co-workers (2002) reported that repeated daily subcutaneous nicotine injections produce regionally selective alterations in rat brain bulk tissue levels of the eCBs, anandamide (AEA), and 2-arachidonoyl glycerol (2-AG), measured 2 h postinjection using mass spectrometry analysis. This technique has been the predominant method for measuring eCB changes, and it allows for rapid evaluation of region-specific effects; however, limitations of this approach (necessary euthanasia, indistinguishable extracellular/intracellular pools) may prevent it from accurately representing synaptically relevant changes (Buczynski and Parsons, 2010). By contrast, *in vivo* microdialysis avoids the requirement for euthanasia before sample collection and better differentiates between extracellular vs intracellular lipid pools. Moreover, microdialysis indexes neuronally

Received 26 June 2012; revised 8 September 2012; accepted 25 September 2012

derived eCB release as demonstrated by tetrodotoxin-sensitive depolarization-induced increases in dialysate AEA and 2-AG levels (Buczynski *et al*, 2010; Giuffrida *et al*, 1999). For these reasons, *in vivo* microdialysis likely provides a more accurate index of drug-induced changes in synaptically relevant eCB levels than do bulk tissue measures.

The volitional nature of nicotine exposure may exert an important influence on nicotine-induced alterations in brain eCB signaling. Substantial evidence demonstrates that volitional (actively intended) drug intake produces distinct physiological, biochemical, and behavioral effects when compared with forced drug administration. For example, the response contingency of drug exposure robustly influences gene expression (Jacobs *et al*, 2002, 2003, 2005), neural activation (Chang *et al*, 1994; Peoples and West, 1996; Stuber *et al*, 2005), and resultant extracellular neurochemistry (Di Ciano *et al*, 1996; Hemby *et al*, 1997; Jacobs *et al*, 2003; Lecca *et al*, 2007; Orejarena *et al*, 2009; You *et al*, 2007). With specific regard to nicotine, differential effects of volitional SA vs forced drug administration have been observed on $\alpha_4\beta_2$ nAChR expression (Metaxas *et al*, 2010), cortical glutamatergic projection activity and plasticity mechanisms in the ventral tegmental area (VTA) (McFarland *et al*, 2003; You *et al*, 2007), and plasma corticosterone levels (Donny *et al*, 2000). Because nAChR, glutamate (GLU), and glucocorticoid signaling robustly influence eCB production (Di *et al*, 2003, 2005; Hill *et al*, 2010a, c), self-administered nicotine may produce distinct effects from forced nicotine exposure on brain eCB signaling.

This study explores the differential effects of volitional nicotine SA and non-volitional forced nicotine administration on brain eCB levels. Rats given access to nicotine SA were compared with rats that received the same history of nicotine infusion patterns using a response-independent yoked administration (YA) design (Hemby *et al*, 1997; Smith *et al*, 1982, 2003). To provide a temporal correlation between drug exposure and changes in brain eCB levels, we employed *in vivo* microdialysis to sample interstitial lipids in the VTA, a region critically involved in the mediation of nicotine reward and addiction (Markou, 2008). For comparative purposes and initial evaluation of regional differences in nicotine-induced changes, an additional study compared the effects of nicotine SA vs YA on brain tissue levels of eCBs and *n*-arachidonoyl conjugates of neurotransmitters (NA-NTs) in the VTA and six additional regions of interest. Overall, the results show that brain eCBs and related lipids are differentially affected by volitional vs forced nicotine administration. Moreover, these findings demonstrate the independent regulation of AEA, 2-AG, palmitoylethanolamide (PEA), OEA, and various NA-NTs, and underscore the differences between *in vivo* microdialysis and post-mortem tissue extractions for indexing levels of neuroactive lipids in the brain.

MATERIALS AND METHODS

Animals

Male Wistar rats (350–450 g; Charles River Laboratories, Wilmington, MA) were housed in a temperature-controlled vivarium (22 °C) with a 12 h light/dark cycle and given *ad libitum* access to water and controlled access to food

(described below). Tests were performed at the beginning of the dark cycle. The studies were conducted in accordance with the NIH Guide for Care and Use of Laboratory Animals.

Surgery

All rats had an intravenous catheter surgically implanted into the jugular vein and were allowed 1 week to recover before experimentation (Caille *et al*, 2007). For microdialysis studies, rats were implanted with a microdialysis guide cannula (SciPro, Sanborn, NY) aimed at the VTA (AP = −4.8 mm, bregma; ML = ± 0.8 mm, bregma; DV = −7.2 mm, dura) (Paxinos and Watson, 1998) before any drug treatment.

Nicotine Administration Procedures

For volitional nicotine exposure, (SA) rats were trained to respond operantly for intravenous nicotine (75 µg/kg per infusion; 0.1 ml per infusion over 4 s) under an FR-1 schedule in daily 2-h sessions using procedures similar to those described previously (Caille *et al*, 2007). Food access was restricted to 10–15 g per rat per day until operant behavior was acquired, and maintained at 25 g per rat per day throughout the remainder of the experiment. Rats receiving non-contingent forced nicotine exposure (YA) were individually paired with animals in the SA group and received an identical pattern of nicotine infusions to their partner rat's SA session from the previous day. Rats receiving acute non-contingent forced nicotine exposure (Acute) were also individually paired with animals in the SA group and received an identical pattern of nicotine infusions only during the final session.

Effect of Nicotine Exposure on Lipid Levels in Regional Brain Bulk Tissue

Rats were given 17 sessions of nicotine SA ($n = 14$) or YA ($n = 12$). A drug-naïve group ($n = 10$) received 17 daily 2-h sessions in which operant responses resulted in intravenous saline infusion (0.1 ml per infusion). At 1 h into the 18th nicotine session, animals were killed by CO₂ asphyxiation and brains were dissected (Supplementary Methods and Supplementary Figure S1) for the prefrontal cortex (PFC), NAc, dorsal striatum (DS), amygdala (AMGY), hippocampus (HIP), VTA, and substantia nigra (SNr). Lipid content was determined using LC-MS/MS (Agilent 6410) multiple-reaction monitoring in positive ion mode. Briefly, 12 tissue lipid species were measured (Supplementary Table S1): 2-AG, AEA, AEA, NA-DA, OL-DA, NA-5HT, PEA, OEA, NE, NA-GLU, NA-aurine (TAU), and NA-γ-aminobutyric acid (GABA). Quantitative analysis was performed by the stable isotope dilution quantification method using internal standards: d₅-2-AG, d₄-AEA, d₄-PEA, and d₄-NA-DA.

Effect of Nicotine Exposure on Lipid Levels Measured by *In Vivo* Microdialysis

Rats were given 36 sessions of nicotine SA ($n = 12$) or YA ($n = 9$). An additional Acute group ($n = 9$) of drug-naïve rats was also prepared. On the evening before microdialysis collections, microdialysis probes (1-mm active membrane)

were inserted through the guide cannulae and perfused overnight with artificial cerebral spinal fluid as described previously (Caille *et al*, 2007). On the subsequent day, dialysate samples were collected at 15-min intervals for 90 min of baseline, 120 min of nicotine exposure (SA, YA, or Acute), and an additional 60 min post-drug. Dialysate eCB levels were analyzed by LC-MS using previously described methods (Caille *et al*, 2007), that is, by using deuterated internal standards (d_4 -AEA, d_4 -PEA, d_4 -OEA, and d_5 -2-AG) and the stable isotope dilution quantification method.

Effect of Nicotine Exposure on FAAH Activity

Rats from the Acute, YA, and SA groups were killed by CO₂ asphyxiation at 2 h after the final nicotine exposure, and their brains snap-frozen and stored at -80°C . Brains were sliced (50 μm) at -10°C to confirm probe placement into the VTA, and the alternate side was sliced (500 μm) and punched for the VTA (Supplementary Methods). Brain punches were processed and analyzed for fatty acid amide hydrolase (FAAH) activity using previously published methodology (Long *et al*, 2009). VTA punches were homogenized in ice-cold PBS, and FAAH activity determined by incubating 100 μl of protein homogenate (0.5 mg/ml, PBS) with 100 μM d_8 -AEA in glass vials (37°C for 30 min). The reaction was quenched with stop solution (300 μl , 2:1 chloroform:methanol, 5 nmol pentadecanoic acid). Samples were vortexed and centrifuged (2400 r.p.m., 4°C , 10 min), and 30 μl of the organic layer was analyzed for d_8 -AEA hydrolysis via single ion monitoring in negative-ion mode using d_8 -arachidonic acid (-311m/z) as the reaction product and pentadecanoic acid (-241m/z) as the internal standard. Data were expressed as relative activity to naïve (control) rats.

Statistics

Statistical analyses were performed using PASW Statistics (Version 18). For tissue lipid data, statistical significance was determined by ANOVA followed by a single false discovery rate analysis (*vs* naïve $*p < 0.05$, *vs* YA $^{\#}p < 0.05$; for details see Supplementary Information; Pike, 2011). For microdialysis lipid data, statistical significance was determined by repeated-measures ANOVA ($*p < 0.05$, $**p < 0.01$, and $***p < 0.001$) for effects of group, nicotine, and group $\times$ nicotine interaction. Here, groups were defined as drug history (Acute *vs* YA) and contingency (YA *vs* SA). Effect of nicotine on each individual condition was determined by ANOVA ($*p < 0.05$, $**p < 0.01$, and $***p < 0.001$). Statistical significance for microdialysis baseline levels and AUC values was determined by ANOVA followed by Fisher's PLSD ($*p < 0.05$, $**p < 0.01$, and $***p < 0.001$).

RESULTS

Effect of Volitional (SA) vs Forced (YA) Nicotine Exposure on VTA eCB and Ethanolamide Levels Measured by *In Vivo* Microdialysis

The SA group ($n = 12$) received a total of 48.6 ± 3.6 mg/kg of nicotine during 36 training sessions, and exhibited stable operant behavior ($\pm 10\%$ for three consecutive sessions) before microdialysis testing. The YA group ($n = 9$) received

49.2 ± 3.7 mg/kg of nicotine over the same number of sessions. During the microdialysis test session, the SA group consumed 1.6 ± 0.3 mg/kg nicotine and the YA and Acute ($n = 9$) groups each received 1.6 ± 0.3 mg/kg nicotine following infusion patterns identical to their paired SA counterparts. The apparent difference in exposure between these groups is related to the differential group sizes.

The experimental design allowed evaluation of the effects of prior nicotine exposure on baseline dialysate lipid levels collected in a nicotine-free state (approximately 48 h after the previous nicotine exposure). There were no significant effects of prior nicotine exposure (either SA or YA) on baseline levels of 2-AG ($F_{(2,29)} = 0.910$; Figure 1a), AEA ($F_{(2,27)} = 0.892$; Figure 2a), or PEA ($F_{(2,28)} = 0.924$; Figure 4d) as compared with levels of these analytes observed in nicotine-naïve rats (eg, the Acute group baseline before nicotine exposure). In contrast, prior nicotine SA experience resulted in reduced baseline dialysate OEA levels ($p < 0.05$) relative to nicotine-naïve controls ($F_{(2,29)} = 3.670$, $p < 0.05$; Figure 4a). While OEA levels trended downward in the YA group, this did not reach statistical significance.

Subsequent nicotine administration significantly increased in VTA dialysate 2-AG content in all groups as determined by repeated-measures ANOVA (Acute ($F_{(8,104)} = 2.519$, $p < 0.005$); YA ($F_{(4,52)} = 2.020$, $p < 0.05$); SA ($F_{(6,78)} = 1.891$, $p < 0.05$; Figure 1b). Comparison of the Acute and YA groups revealed an effect of nicotine ($F_{(1,13)} = 3.825$, $p < 0.001$) and drug history ($F_{(1,13)} = 7.668$, $p < 0.05$), as well as an interaction between these factors ($F_{(13,143)} = 2.752$, $p < 0.005$). Comparison of SA and YA groups revealed an effect of nicotine ($F_{(1,13)} = 3.886$, $p < 0.001$), but no significant effect of response contingency ($F_{(1,13)} = 0.993$, NS) or interaction between these factors ($F_{(8,143)} = 1.263$, NS). Thus, although prior drug history significantly alters nicotine-induced increases in VTA 2-AG levels, the volitional nature of repeated drug exposure does not significantly influence nicotine-induced increases in VTA 2-AG. However, no significant group differences were evident on comparison of composite AUC indices of the nicotine administration period (Figure 1c).

Nicotine administration produced distinct effects on VTA dialysate AEA content according to both drug history and response contingency (Figure 2b). Based on repeated-measures ANOVA, forced nicotine administration significantly decreased dialysate AEA in the Acute group ($F_{(5,65)} = 4.298$, $p < 0.001$), although no changes in dialysate AEA were evident in the YA group ($F_{(6,78)} = 0.953$, NS). Although no effect of drug history was evident on comparison of composite AUC measures of the Acute and YA groups (Figure 2c), two-way repeated-measures ANOVA revealed a significant interaction between drug history and nicotine effects ($F_{(13,143)} = 2.441$, $p < 0.01$). Comparison of effects in the YA and SA groups that had an identical history of nicotine exposure revealed a significant influence of response contingency. In contrast to the lack of nicotine effects in the YA group, dialysate AEA levels were significantly increased by nicotine SA ($F_{(10,130)} = 2.109$, $p < 0.05$), and two-way ANOVA revealed a significant interaction between response contingency and nicotine effects ($F_{(13,208)} = 2.441$, $p < 0.05$). This distinction was further validated by a significantly greater composite AUC value in the SA *vs* YA group ($F_{(1,19)} = 4.770$, $p < 0.05$).

Figure 1 Effects of volitional nicotine self-administration (SA) and forced nicotine yoked administration (YA) on dialysate 2-arachidonoyl glycerol (2-AG) levels collected from the rat ventral tegmental area (VTA). For evaluation of the effects of repeated nicotine exposure, a comparative group receiving non-contingent YA for the first time (Acute) was also presented. The SA ($n = 12$) group lever pressed for nicotine infusions during the session, while the YA ($n = 11$) and Acute ($n = 9$) groups received response-independent nicotine infusions following a temporal pattern tied to the SA group (eg, YA design). There were no significant effects of prior nicotine exposure on baseline 2-AG levels, regardless of response contingency (a). Intravenous nicotine delivery significantly increased dialysate 2-AG levels in all groups, regardless of response contingency or prior history with the drug (b (temporal profile) and c (total response indexed by area under the curve (AUC))). Significance for baseline and AUC was determined by analysis of variance (ANOVA) followed by Fisher's protected least significant difference (PLSD) (* $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$). Significance for group effects of time was determined by repeated-measures ANOVA and indicated in the group legend of panel b (* $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$). NS, nonsignificant.

Figure 2 Effects of volitional nicotine self-administration (SA) vs forced nicotine yoked administration (YA) on ventral tegmental area (VTA) dialysate anandamide (AEA) levels. Effects of repeated nicotine exposure are indexed by comparison of AEA responses to Acute vs repeated (YA) non-contingent nicotine exposure. There were no significant effects of prior nicotine exposure on baseline AEA levels, regardless of response contingency (a). Volitional nicotine SA ($n = 12$) significantly increased dialysate AEA levels, although response-independent nicotine infusions did not alter dialysate AEA in YA animals ($n = 11$). Drug-naïve animals receiving nicotine for the first time (Acute; $n = 9$) displayed reduced AEA levels following nicotine exposure (b and c). Statistical evaluations and levels of significance are as described in the legend for Figure 1. NS, nonsignificant.

Nicotine did not significantly alter VTA dialysate levels of either OEA or PEA during the exposure session under any of the conditions evaluated. Specifically, for OEA (Figure 3b) there were no significant effects of drug history (Acute vs YA: history ($F_{(1,9)} = 0.024$, NS); nicotine ($F_{(1,13)} = 0.430$, NS); and interaction ($F_{(13,117)} = 0.363$, NS)) or response contingency (YA vs SA: contingency ($F_{(1,13)} = 1.602$, NS); nicotine ($F_{(1,13)} = 1.660$, NS); and interaction ($F_{(13,169)} = 0.628$, NS)). It is worth noting that the significantly lower baseline OEA levels in the SA group amplifies the apparent effect of nicotine when expressed as the percent change from baseline (Figure 3b). When considered as the change in absolute dialysate concentration, nicotine YA and SA produce nearly identical profiles (not shown). Analyses of nicotine-induced alterations in dialysate OEA fail to reach significance, regardless of the analysis by either the change in absolute concentration or the percent change from pre-nicotine baseline. For PEA (Figure 3e), there were no significant effects of drug history (Acute vs YA: history ($F_{(1,12)} = 0.017$, NS); nicotine ($F_{(1,13)} = 1.513$, NS); and interaction ($F_{(13,156)} = 0.559$, NS)) or response contingency (YA vs SA: contingency ($F_{(1,15)} = 0.228$, NS); nicotine ($F_{(1,13)} = 1.202$, NS); and interaction ($F_{(13,195)} = 1.140$, NS)). Similarly, no group differences were

evident on comparison of composite AUC indices of OEA or PEA effects during the nicotine administration period (Figure 3e and f, respectively).

Effect of Volitional (SA) vs Forced (YA) Nicotine Exposure on eCB, Ethanolamide, and NA-NT Levels in Regional Brain Tissue Samples

Rats in the SA group ($n = 14$) acquired stable levels of nicotine intake within 8 training sessions and received a total of 16.0 ± 1.6 mg/kg of nicotine over 17 sessions of drug training; 0.66 ± 0.06 mg/kg nicotine was consumed during the final session before being killed. Animals in the YA group ($n = 10$) received 16.6 ± 1.8 mg/kg of nicotine over the course of the 17 sessions and 0.68 ± 0.06 mg/kg during the final session.

Chronic intravenous nicotine exposure increased VTA tissue AEA content without altering VTA 2-AG or ethanolamide content (Figure 4a). Specifically, VTA AEA content was higher in nicotine-exposed animals with slightly higher increases evident in the YA ($p < 0.001$ vs naïve) vs the SA ($p < 0.01$ vs naïve, $p < 0.01$ vs YA) groups. No detectable group differences were evident for OEA, PEA, or 2-AG content in VTA tissue (Figure 4b–d). With regard to the

Figure 3 Effects of volitional nicotine self-administration (SA) vs forced nicotine yoked administration (YA) on ventral tegmental area (VTA) dialysate oleylethanolamide (OEA) and palmitoylethanolamide (PEA) levels. Effects of repeated nicotine exposure are indexed by comparison of OEA responses to Acute vs repeated (YA) non-contingent nicotine exposure. Baseline OEA levels were significantly lower in VTA dialysates from animals with a history of nicotine SA ($n = 12$) as compared with nicotine-naïve controls ($n = 9$; a). Baseline OEA levels in rats with a history of forced nicotine exposure (YA; $n = 11$) also tended to be lower than controls, although this did not reach significance. Dialysate OEA content was unaltered during nicotine exposure, regardless of drug history or response contingency (b and c). There was no significant effect of prior nicotine exposure on baseline PEA levels, regardless of response contingency (d). Dialysate PEA content was unaltered during nicotine exposure, regardless of drug history or response contingency (e and f). Statistical evaluations and levels of significance are as described in the legend for Figure 1. NS, nonsignificant.

Figure 4 Effects of volitional (self-administration (SA); $n = 14$) and forced (yoked administration (YA); $n = 12$) nicotine exposure on ventral tegmental area (VTA) tissue (a) anandamide (AEA), (b) 2-arachidonoyl glycerol (2-AG), (c) oleylethanolamide (OEA), and (d) palmitoylethanolamide (PEA) content as compared with levels of these analytes in VTA tissue of nicotine-naïve controls (indexed by lipid extracts from bulk tissue quantified by liquid chromatography-tandem mass spectrometry (LC-MS/MS)). VTA AEA content was significantly increased by both volitional (SA) and forced (YA) nicotine exposure relative to levels in drug-naïve controls ($n = 10$), although YA exposure resulted in significantly greater increases than SA exposure. No significant nicotine-related changes in 2-AG, OEA, or PEA levels were evident in either SA or YA groups relative to drug-naïve controls. Significance was determined by analysis of variance (ANOVA) followed by a single false discovery rate analysis (vs control * $p < 0.05$, vs SA # $p < 0.05$).

Figure 5 Effects of volitional (self-administration (SA); $n = 14$) and forced (yoked administration (YA); $n = 12$) nicotine exposure on regional brain tissue *n*-arachidonoyl conjugates of neurotransmitters (NA-NT) content as compared with levels of these analytes in nicotine-naïve controls (indexed by lipid extracts from bulk tissue quantified by liquid chromatography-tandem mass spectrometry (LC-MS/MS)). (a) Prefrontal cortex (PFC) NA- γ -aminobutyric acid (GABA) content was significantly increased by both volitional (SA) and forced (YA) nicotine exposure relative to levels in drug-naïve controls ($n = 10$), although YA exposure resulted in significantly greater increases than SA exposure. (b) Nucleus accumbens (NAc) NA-glutamate (GLU) and (c) dorsal striatum (DS) NA-taurine (TAU) content were significantly increased by YA nicotine exposure relative to levels in drug-naïve controls. No significant nicotine-related changes of DS NA-DA levels were evident in either SA or YA groups relative to drug-naïve controls (d). Significance was determined by analysis of variance (ANOVA) followed by a single false discovery rate analysis (vs control * $p < 0.05$, vs SA # $p < 0.05$).

other brain regions evaluated, YA generally produced greater increases in AEA content than SA did (Table 1). For example, nicotine-induced increases in tissue AEA content in the NAc ($p < 0.001$), SNr ($p < 0.05$), PFC ($p < 0.01$), and AMYG ($p < 0.01$) were solely attributable to the YA group. In fact, YA increased SNr AEA content by nearly fivefold, the largest recorded change in this experiment, yet no corresponding alteration occurred in the SA group.

Interestingly, chronic nicotine exposure altered bulk tissue levels of a number of NA-NTs (Figure 5). Levels of NA-GABA increased in the PFC following both SA ($p < 0.01$) and YA ($p < 0.001$). In contrast, while nicotine SA was not associated with alterations in NA-GLU or NA-TAU, nicotine YA increased NA-GLU in the NAc ($p < 0.01$) and SNr ($p < 0.01$), as well as NA-TAU in the DS ($p < 0.01$) and SNr ($p < 0.001$). NA-DA was detected exclusively in the DS, but chronic nicotine exposure did not alter bulk tissue levels. Each of the seven brain regions in this study exhibited a unique profile of changes in at least one of the nine lipid species identified in bulk tissue, as illustrated in the complete data set from this experiment (Table 1).

Effect of Nicotine Exposure on FAAH Activity in the VTA

Following the microdialysis session, a representative subset of rats from the SA group (51.3 ± 2.8 mg/kg of total nicotine history), YA group (51.3 ± 3.1 mg/kg of total nicotine history), and Acute group (1.6 ± 0.3 mg/kg nicotine) were analyzed for FAAH activity in the VTA. Endogenous FAAH

activity in the VTA from drug-naïve rats produced 1770 ± 200 pmol/mg of tissue, comparable to previous work measuring FAAH activity in the AMYG (Hill *et al*, 2009). Relative to drug-naïve animals ($100 \pm 11\%$, $n = 7$), there was no significant effect of nicotine in any of the Acute ($108 \pm 9\%$, $n = 7$), YA ($90 \pm 8\%$, $n = 6$), or SA ($99 \pm 14\%$, $n = 7$) exposure groups as determined by ANOVA.

DISCUSSION

The present observations highlight the independent regulation of 2-AG, AEA, and OEA levels in the VTA in response to nicotine administration, consistent with prior reports of differential alterations in interstitial 2-AG and AEA by other drugs of abuse (Alvarez-Jaimes *et al*, 2009; Caille *et al*, 2007). The data also reveal distinct influences of nicotine SA vs forced nicotine administration on interstitial AEA and OEA levels and underscore the differences between *in vivo* microdialysis and post-mortem tissue extractions for indexing levels of neuroactive lipids in the brain.

Functional Implications of Distinct Nicotine-Induced Effects on 2-AG, AEA, and OEA

Nicotine increased VTA dialysate 2-AG levels under every administration condition evaluated (Acute, YA, and SA). This consequence of nicotine exposure may be of substantial import as 2-AG has a key role in the plasticity of GLU signaling onto VTA DA neurons (Haj-Dahmane and

All lipids expressed as pmol/g, except 2-AG (nmol/g); not detected was indicated by —; vs naïve **p* < 0.05, vs YA [#]*p* < 0.05; naïve (*n* = 10), YA (*n* = 12), SA (*n* = 14).

Shen, 2010; Kortleven *et al*, 2011), which is thought to be a critical component of tobacco addiction (Mansvelter *et al*, 2009). Moreover, increased 2-AG signaling in the VTA potentiates cue-evoked increases in the NAc DA and associated reward-seeking (Oleson *et al*, 2012), and this may participate in the well-known enhancement of cue conditioning that contributes to nicotine reward (Caggiula *et al*, 2002; Chaudhri *et al*, 2006). Nicotine-induced elevations in VTA 2-AG were enhanced following repeated drug exposure, and no differences were evident in the 2-AG response to nicotine SA vs YA. This is consistent with a 2-AG involvement in nicotine-induced VTA synaptic plasticity and enhancement of cue conditioning as both of these processes increase with repeated nicotine exposure with comparable effects being evident following either SA or forced nicotine administration.

Nicotine SA induced significant increases in dialysate AEA content, although no change in AEA levels were evident during nicotine YA. Relatively little is known regarding the influence of AEA signaling on VTA neurophysiology. Increased VTA AEA signaling may enhance DA cell activity through at least two mechanisms, including CB₁-mediated decreases in presynaptic GABA release (Lupica and Riegel, 2005; Szabo *et al*, 2002) and increased GLU release via activation of transient receptor potential vanilloid 1 (TRPV₁) receptors on glutamatergic terminals (Marinelli *et al*, 2005). In contrast, CB₁-mediated suppression of VTA GLU release has also been reported (Lupica *et al*, 2005; Melis *et al*, 2004), and this may contribute to the reported CB₁-mediated attenuation of nicotine-induced

excitation of VTA DA cells evident following FAAH inhibition (Melis *et al*, 2008). It is presently unclear which of these mechanisms prevails in propagating AEA signaling during nicotine SA.

Nicotine SA, but not YA, resulted in selective deficits in baseline interstitial OEA levels in the VTA, implicating the volitional nature of drug intake on this effect. Although OEA has no significant activity in the CB₁ receptors, it strongly activates peroxisome proliferator-activated receptor α (PPAR α) signaling *in vivo* (Fu *et al*, 2003). PPAR α activation by OEA and other agonists reduces nicotine SA, prevents nicotine-induced increases in VTA DA cell burst firing, and attenuates nicotine-induced increases in NAc DA release (Mascia *et al*, 2010, 2011; Melis *et al*, 2008). PPAR α receptors can exert tonic inhibition of DA cell activity, as their antagonism increases the spontaneous firing rate of VTA DA neurons (Melis *et al*, 2010). Accordingly, deficient OEA tone may contribute to enhanced spontaneous firing and burst activity of VTA DA cells that is more pronounced following a history of nicotine SA vs YA (Caille *et al*, 2009). The PPAR α influence on VTA DA cell activity likely occurs through a negative modulation of $\alpha_4\beta_2$ -nACh receptor expression or function (Melis *et al*, 2010), and it is conceivable that reduced PPAR α activation resulting from deficient OEA tone contributes to enhanced VTA $\alpha_4\beta_2$ -nACh receptor expression that is more pronounced following nicotine SA vs YA (Metaxas *et al*, 2010). Although nicotine SA produced subtle nonsignificant elevations in dialysate OEA content, this was not sufficient to restore OEA to levels observed in nicotine-naïve controls.

The present findings provide additional indication of the complex influence of cannabinoid and ethanolamide signaling on nicotine-taking and nicotine-seeking behaviors. For example, although synthetic CB₁ agonists increase nicotine SA and enhance nicotine-seeking behavior (Gamaledin *et al*, 2012), these nicotine-related behaviors are generally attenuated by enhancing endogenous eCB tone (eg, eCB clearance inhibition) (Forget *et al*, 2009; Gamaledin *et al*, 2011; Scherma *et al*, 2008). The distinction between these influences may arise, in part, from differential regional patterns of CB₁ activation. While exogenous agonists induce widespread CB₁ activation, eCB clearance inhibition likely results in regionally restricted CB₁ activation created by region-specific differences in nicotine-induced eCB formation and/or eCB modulations induced by nicotine-seeking. Moreover, in contrast to CB₁-selective agonists, manipulations such as FAAH inhibition also enhance signaling through non-CB receptors (PPAR α , TRPV₁, and so on) that may counter or modify the effects of concurrent CB₁ receptor signaling. Because the nature of nicotine-induced alterations in eCB signaling may differ at various stages of nicotine exposure (eg, acquisition *vs* maintenance of drug intake; dependence), and nicotine-induced eCB alterations may differ from eCB disruptions associated with nicotine-seeking behavior (induced by cues, drug priming, and/or stress), it is not surprising that the influence of eCB clearance inhibition on nicotine-related behaviors varies among these distinct phases of nicotine use (Forget *et al*, 2009; Scherma *et al*, 2008).

Potential Mechanisms for the Distinct Influence of Nicotine SA and YA on VTA eCBs

As described above, we find that a history of volitional nicotine SA exerts greater effects on basal OEA levels as compared with forced nicotine YA. In a somewhat similar manner, we find that VTA AEA levels are more potently increased by nicotine SA *vs* YA (which did not alter dialysate AEA). Tendencies toward greater effects of nicotine SA *vs* YA on dialysate OEA and PEA were also evident, although this did not reach significance. In contrast, dialysate 2-AG levels were enhanced during both SA and YA (compared with Acute exposure) and there were no significant between-group differences in this effect. Because AEA, OEA, and PEA are degraded through a common mechanism (FAAH), while 2-AG is degraded through a distinct route (hydrolysis by monoacylglycerol lipase, MAGL), it could be argued that FAAH and MAGL activities are differentially influenced by the volitional nature of nicotine administration. However, we found no significant differences in FAAH activity in VTA tissue from animals in the SA, YA, or Acute groups as compared with nicotine-naïve controls. Moreover, because FAAH exerts comparable hydrolytic activity on AEA, OEA, and PEA, the data demonstrating an independent regulation of these ethanolamides argues against a substantial influence of SA-*vs* YA-induced disruptions in FAAH activity.

Alternately, volitional *vs* forced nicotine administration may differentially influence the mechanisms contributing to the formation of AEA and related ethanolamides. Unfortunately, several limitations hinder the ability to probe for group-related differences in AEA biosynthesis. For example,

the pathway(s) for AEA synthesis have not been unequivocally identified (Leung *et al*, 2006; Simon and Cravatt, 2008; Liu *et al*, 2008), and there are presently no selective inhibitors available for any of the enzymes implicated in AEA biosynthesis. The volitional nature of nicotine exposure may also influence the neurochemical stimuli that provoke AEA production. For example, nicotine SA and YA produce distinct alterations in nAChR expression, DA D₂ receptor binding, and corticosterone levels (Caille *et al*, 2009; Donny *et al*, 2000; Metaxas *et al*, 2010), and each of these systems can influence the production of AEA and related ethanolamides (Centonze *et al*, 2004; Di *et al*, 2003, 2005; Giuffrida *et al*, 1999; Hill *et al*, 2010a, b; Stella and Piomelli, 2001).

Further work is needed to characterize which, if any, of these neurochemical mechanisms underlie the distinct effects of nicotine SA and YA on AEA and related ethanolamides. Extensive evidence implicates mGluR₅ and other postsynaptic G_q-coupled receptors in the activation of diacylglycerol lipase α involved in 2-AG formation (Jung *et al*, 2005), although the relative influence of volitional *vs* forced nicotine administration on these and related G_q-coupled receptors have not been investigated. It is conceivable, however, that diminished 2-AG formation has a role in the attenuation of nicotine SA behavior induced by mGluR₅ antagonists (D'Souza and Markou, 2011; Tronci and Balfour, 2011).

The Volitional Nature of Nicotine Exposure also Influences Brain Bulk Tissue Lipids

Consistent with the microdialysis results discussed above, nicotine SA and YA were found to induce distinct effects on eCB levels extracted from post-mortem brain tissue. Similar to the microdialysis results, the distinction between the effects of SA and YA was evident in measures of tissue AEA, but not 2-AG, OEA, or PEA. The differential influence of SA *vs* YA on tissue AEA levels was present in VTA, as well as the SNr and NAc. In contrast to the microdialysis results, nicotine YA induced greater increases in tissue AEA than nicotine SA; this was evident in the VTA, SNc, and NAc, with similar trends observed in the DS and PFC. In further contrast to the microdialysis results, no effect of nicotine administration on tissue 2-AG content was evident in any region evaluated, regardless of the nature of nicotine exposure (eg, SA *vs* YA). Although animals in the tissue extraction study received less total nicotine exposure than their counterparts in the microdialysis study, the significant effect of nicotine on dialysate 2-AG during the first nicotine exposure suggests that differences in nicotine history do not explain the disparity between the microdialysis and tissue extraction studies.

Several distinctions between these eCB sampling techniques may contribute to the dissimilar profiles provided by *in vivo* microdialysis and post-mortem brain tissue lipid extraction procedures (Buczynski *et al*, 2010). For example, robust post-mortal increases in brain tissue AEA and 2-AG content have been shown to occur even within 30 s of death (see Buczynski and Parsons (2010) for discussion), and this may be related to or exacerbated by several factors, including the stress and ischemia associated with CO₂ euthanasia. These effects may interact with processes

engaged by the pre-euthanasia manipulation (nicotine exposure itself and possible stress associated with removal from the nicotine-exposure chamber) to distort the perceived effects of the manipulation. Subtle nicotine-induced alterations in neuronally derived eCB or ethanolamide production may also be overshadowed by post-mortem lipid accumulation and/or the contribution of non-neuronal eCB and ethanolamide sources that are unavoidably indexed by tissue extraction procedures. This latter possibility may explain the lack of evidence for nicotine-induced alterations in brain 2-AG levels in the tissue extraction experiment. These issues highlight an important advantage of *in vivo* microdialysis wherein brain eCB levels are monitored in awake and freely moving animals. Nonetheless, brain tissue analysis allow for rapid characterization of region-specific alterations in eCB content and provide an index of manipulation-induced alterations in eCB production (with acknowledgment of the caveats discussed above). In this regard, the present tissue data reinforce the conclusion that the nature of nicotine exposure (SA vs YA) can differentially influence brain eCB levels and provide evidence for nicotine-induced disruptions eCB, ethanolamide, and as discussed below NA-NT levels in the VTA and other regions of the mesocortico-limbic system.

Although a role for NA-NTs in drug-related behavior has not been established, the present data demonstrate robust, regionally distinct alterations in brain tissue NA-NT content following chronic nicotine exposure, including alterations in NA-GLU, NA-GABA, and NA-TAU. Recent studies suggest that some NA-NTs such as NA-DA originate from the direct conjugation of the parent transmitter to arachidonic acid (Hu *et al*, 2009). A common biosynthetic mechanism could suggest that regional levels depend on the relative amount of available NT. In support of this notion, we find that NA-TAU and NA-GLU exhibit a 100-fold range in regional levels, and detectable levels of NA-DA were present only in the DS. This contrasts with relatively stable levels of AEA and 2-AG content, which vary <2-fold across brain regions. As a class, NA-NTs are considered as potential ligands for T-type calcium channels (Barbara *et al*, 2009; Ross *et al*, 2009), TRP receptors (Saghatelian *et al*, 2006), and GPCRs (Bradshaw *et al*, 2009). To this end, identifying their endogenous target receptors and assessment of their signaling competent levels by microdialysis represent important objectives. Indeed, based on their susceptibility to nicotine exposure and their regional disparity, they represent an interesting area for future research.

In conclusion, the present results demonstrate that nicotine differentially modulates brain levels of 2-AG, AEA, and OEA, and that the nature of these modulations can be influenced by the volitional nature of the drug exposure. As indexed by VTA microdialysis, nicotine SA induced greater decrements in baseline OEA levels and greater drug-induced increases in AEA levels than did forced YA. Each of these effects may contribute to enhanced activity and excitability of VTA DA neurons evident following chronic self-administered, but not forced, nicotine exposure (Caille *et al*, 2009; Metaxas *et al*, 2010), an effect that likely enhances both the direct and conditioned reinforcing effects of the drug. The present data also

demonstrate that nicotine-induced increases in VTA 2-AG levels are influenced by drug history, but not by response contingency. Nicotine-induced increases in 2-AG signaling may contribute to CB₁-mediated synaptic plasticity and conditioning effects that have an important role in tobacco dependence but are not influenced the volitional nature of nicotine exposure. Collectively, these findings highlight the independent regulation of 2-AG, AEA, and OEA signaling in the brain and underscore the importance of incorporating volitional control of drug intake in the characterization of drug-induced alterations in eCB signaling.

ACKNOWLEDGEMENTS

This is manuscript number 21701 from The Scripps Research Institute. We thank Dr Jonathan Z Long and Ryan B Lamer for the synthesis and purification of *n*-arachidonoyl GLU, Dr Benjamin F Cravatt for access to mass spectrometry instrumentation, and Dr Nimish Sidh-pura for helpful discussions and assistance in preparing the manuscript. This work was supported by NIDA Grants P01 DA017259 (LHP) and F32 DA029994 (MWB).

DISCLOSURE

The authors declare no conflict of interest.
