The potential involvement of the cannabinoid CB₂ receptors (CB₂r) in the adaptive responses induced by cocaine was studied in transgenic mice overexpressing the CB₂r (CB₂xP) and in wild-type (WT) littermates. For this purpose, the acute and sensitized locomotor responses to cocaine, conditioned place preference, and cocaine intravenous self-administration were evaluated. In addition, we assessed whether CB₂r were localized in neurons and/or astrocytes, and whether they colocalized with dopamine D1 and D2 receptors (D1Dr and D2Dr). Dopamine (DA) extracellular levels in the nucleus accumbens (NAcc), and gene expression of tyrosine hydroxylase (TH) and DA transporter (DAT) in the ventral tegmental area (VTA), and μ -opioid and cannabinoid CB₁ receptors in the NAcc were also studied in both genotypes. CB₂xP mice showed decreased motor response to acute administration of cocaine (10–20 mg/kg) and cocaine-induced motor sensitization compared with WT mice. CB₂xP mice presented cocaine-induced conditioned place aversion and self-administered less cocaine than WT mice. CB₂r were found in neurons and astrocytes and colocalized with D2Dr in the VTA and NAcc. No significant differences in extracellular DA levels in the NAcc were observed between genotypes after cocaine administration. Under baseline conditions, TH and DAT gene expression was higher and μ -opioid receptor gene expression was lower in CB₂xP than in WT mice. However, both genotypes showed similar changes in TH and μ -opioid receptor gene expression after cocaine challenge independently of the pretreatment received. Importantly, the cocaine challenge decreased DAT gene expression to a lesser extent in cocaine-pretreated CB₂xP than in cocaine-pretreated WT mice. These results revealed that CB₂r are involved in cocaine motor responses and cocaine self-administration, suggesting that this receptor could represent a promising target to develop novel treatments for cocaine addiction.

Neuropsychopharmacology (2012) **37**, 1749–1763; doi:10.1038/npp.2012.22; published online 14 March 2012

Keywords: cocaine; cannabinoid; dopamine transporter; sensitization; self-administration; tyrosine hydroxylase

INTRODUCTION

A large body of evidence suggests the involvement of the endocannabinoid system (ECS) in the development of dependence to different licit and illicit drugs (Fattore *et al*, 2007; Lupica *et al*, 2004; Maldonado *et al*, 2006; Parolaro and

Rubino, 2008; Tanda and Goldberg, 2003). However, the specific participation of the ECS in cocaine addiction remains unclear. Thus, the administration of a cannabinoid CB₁ receptor (CB₁r) antagonist or the deletion of CB₁r does not alter cocaine self-administration in rodents (Cossu *et al*, 2001), conditioned place preference (CPP) or behavioral sensitization (Lesscher *et al*, 2005; Martin *et al*, 2000). Other studies revealed that the administration of a cannabinoid CB₁r agonist induced relapse to cocaine-seeking behavior (De Vries *et al*, 2001), and CB₁r antagonists inhibited sensitized locomotor response to a cocaine challenge (Filip *et al*, 2006) and cocaine self-administration (Soria *et al*, 2005; Xi *et al*, 2008). In addition, the deletion of CB₁r

Received 5 August 2011; revised 10 February 2012; accepted 13 February 2012

decreased cocaine-induced motor sensitization (Corbille *et al*, 2007), CPP (Miller *et al*, 2008) and the breakpoint for cocaine self-administration (Soria *et al*, 2005).

There is scarce information about the possible involvement of cannabinoid CB₂ receptors (CB₂r) in cocaine dependence. Initially, CB₂r were found in the brain only under pathological conditions (Ehrhart *et al*, 2005; Guzman *et al*, 2001; Ibrahim *et al*, 2003). However, further descriptive studies in rodents reported CB₂r gene expression in the different areas of brain under baseline conditions, caudate putamen, nucleus accumbens (NAcc), cingulate cortex, amygdala, hippocampus, ventromedial hypothalamic nucleus, arcuate nucleus, thalamus, substantia nigra, dorsal raphe, and medial raphe nucleus (Garcia-Gutierrez *et al*, 2010; Onaivi, 2006; Van Sickle *et al*, 2005). Furthermore, the presence of CB₂r in reward-related brain areas such as the ventral tegmental area (VTA) and the NAcc suggests the participation of this receptor in drug abuse.

A number of results support the potential implication of CB₂r in addictive behaviors. Increased CB₂r gene expression was reported in the brain of mice after chronic treatment with heroin or cocaine (Onaivi *et al*, 2008). In contrast, the same group reported reduced CB₂r gene expression in striatum and ventral midbrain after chronic ethanol intake in mice (Onaivi *et al*, 2008). Furthermore, the pharmacological manipulation of CB₂r modified ethanol intake only in stressed mice (Ishiguro *et al*, 2007). It is possible that CB₂r and CB₁r function together regulating dopaminergic circuits involved in drug-induced motivation and reward. Drugs of abuse act directly on dopaminergic terminals or block GABAergic inhibitory neurons on cell bodies of mesolimbic dopaminergic neurons, increasing the release of dopamine (DA) in the NAcc (Nestler, 2001; Spanagel and Weiss, 1999; Tanda *et al*, 1997). In contrast, drug withdrawal decreases mesolimbic DA neuronal activity (Spanagel and Weiss, 1999), reduces spontaneous firing rate of DA neurons in the VTA (Diana *et al*, 1998), and decreases tyrosine hydroxylase (TH) gene expression in the VTA (Oliva *et al*, 2003). The regulation of DA neuronal activity involves the participation of the DA transporter (DAT), which regulates DA reuptake from the synaptic cleft determining the intensity and duration of DA activity (Gainetdinov *et al*, 2003; Jaber *et al*, 1997) and TH, the rate-limiting enzyme of DA biosynthesis (Jaber *et al*, 1999; Jones *et al*, 1998). In addition, several reports revealed the participation of the μ -opioid receptor (Chefer *et al*, 2004; Hall *et al*, 2004; Hummel *et al*, 2004; Yoo *et al*, 2003) and the CB₁r in the relapse to cocaine-seeking (De Vries *et al*, 2001) and in the rewarding effects of other drugs of abuse (Onaivi, 2008; Parolaro and Rubino, 2008), suggesting a functional interaction between opioid and cannabinoid systems in addiction-related behavioral responses (Manzanares *et al*, 1999; Navarro *et al*, 2001; Paldyova *et al*, 2008).

To explore the potential involvement of CB₂r in the adaptive responses underlying addictive processes, several behavioral and neurochemical responses induced by cocaine were studied in the wild-type (WT) and transgenic mice overexpressing CB₂r (CB₂xP). The overexpression of CB₂r in CB₂xP mice has been identified in caudate putamen (150%), NAcc (180%), cingulate cortex (199%), amygdala (64%), hippocampus (158%), ventromedial thalamic nucleus (126%), arcuate nucleus (157%), substantia nigra

(278%), VTA (100%), dorsal raphe (50%), and medial raphe nucleus (57%) compared with WT mice (Garcia-Gutierrez *et al*, 2010). We evaluated acute dose-response effects of cocaine on motor activity, sensitization to cocaine-induced motor effects, CPP, and intravenous cocaine self-administration under both fixed ratio (FR) and progressive ratio (PR) schedules of reinforcement, as well as *in vivo* microdialysis following acute cocaine administration in both genotypes. In addition, cells expressing CB₂r were phenotypically characterized using double immunolabeling. Finally, TH and DAT, as well as CB₁r and μ -opioid receptor gene expression was also measured in the VTA and NAcc, respectively.

MATERIALS AND METHODS

Animals

Male CB₂xP mice were generated in our laboratory, as described previously (Racz *et al*, 2008), and their corresponding WT littermates (25–35 g bw) were used in all the experiments.

Animals were maintained in a temperature- ($21 \pm 1^\circ\text{C}$) and humidity- ($65 \pm 10\%$) controlled room with a light-dark cycle (lights on from 0800 to 2000 hours) except for the self-administration studies where a reversed light-dark cycle (lights off from 0800 to 2000 hours) was used. Behavioral tests and animal care were conducted in accordance with the standard ethical guidelines (National Institutes of Health, 1995; European Commission Directive 86/609 EC) and approved by the local ethical committee (CEE-IMAS-UPF/UMH). All behavioral experiments were performed under blind conditions.

Drugs

Cocaine hydrochloride was obtained from The Spanish Agency of Drugs (AGEMED, Madrid, Spain), dissolved in sterile saline and administered 10–40 mg/kg (i.p.; 0.3 ml) or 0.5 mg/kg (i.v.; per infusion).

Acute Motor Effects Induced by Cocaine

The motor response was evaluated in the open-field test. Mice were individually placed in a transparent square cage (25 × 25 × 25 cm; Urigüen *et al*, 2004) and the traveled distance was recorded 10 min after cocaine (10, 20 and 40 mg/kg) or saline administration with a video camera during a period of 20-min and analyzed using the SMART (Spontaneous Motor Activity Recording and Tracking) software system (Panlab, Barcelona, Spain). For details about SMART software see Supplementary Information.

Sensitization to Motor Response Induced by Cocaine

Mice from both genotypes were selected and divided in three groups receiving saline or cocaine (10 or 20 mg/kg, i.p., once daily) for 20 consecutive days. The evaluation of motor sensitization was carried out measuring the traveled distance by mice in the open-field test for 20 min, under baseline conditions, and 10 min after cocaine/saline administration on days 1, 10, and 20 using the SMART software.

After the last cocaine administration on day 20, mice remained abstinent for the next 6 days. On day 27, mice were challenged with cocaine (10 and 20 mg/kg, i.p.) or saline and the motor activity was measured again.

Conditioned Place Preference

WT and CB₂xP mice were evaluated in a CPP for cocaine (20 mg/kg; i.p.). Details of the features of the apparatus and the procedure used are described in Supplementary Information.

Cocaine Self-Administration

Details of the features of the apparatus and surgical procedures are described in the Supplementary Information.

Drug self-administration procedure. Four days after surgery, CB₂xP and WT mice were trained to nose-poke under a FR1 schedule of reinforcement in order to receive cocaine (0.5 mg/kg/infusion) for 10 consecutive days, as previously described (Soria *et al*, 2005). Self-administration sessions starting with a priming injection of the drug (0.5 mg/kg/infusion) lasted for 60 min daily and were conducted 6 days per week. After each session, mice were returned to their home-cages. The number of reinforcers was limited to 50 infusions per session. Each infusion was followed by a 15-s time-out period during which an active nose-poke had no consequence. Stable acquisition of self-administration behavior was achieved when all of the following conditions were met: (i) < 20% deviation from the mean of the total number of reinforcers earned in three consecutive sessions (80% stability), (ii) at least 75% responding on the active hole, and (iii) a minimum of 10 reinforcers earned per session. When stability was acquired, mice were tested on a PR schedule of reinforcement, where the requirement to earn an injection escalated according to the following series: 1–2–3–5–12–18–27–40–60–90–135–200–300–450–675–1000 (Soria *et al*, 2005).

Water-maintained operant behavior. Mice were first deprived of water (20 min of free water was provided daily) for 2 days and this water deprivation regimen was maintained during the whole evaluation of water-maintained operant behavior. Food was available *ad libitum* during the whole experiment. Two days after starting water deprivation, mice were trained to nose-poke for water under a FR1 schedule of reinforcement, as previously described (Trigo *et al*, 2007). Responses were maintained by water delivered in 10 µl over 10 s, and a time-out period of 20 s was established after each reinforce. The session was terminated after 100 reinforcers were delivered or after 1 h, whichever occurred first. Mice achieving the acquisition criteria underwent a PR schedule of reinforcement, as reported for drug self-administration.

Immunohistochemistry

WT and CB₂xP mice were perfused with 4% paraformaldehyde, 0.002% CaCl₂ in 0.1 M phosphate buffer (PB; pH

7.3–7.4) for 15 min. Coronal sections (60 µm-thick) were obtained at 0.98–1.70 mm from bregma, containing the NAcc, and at –2.54 to –2.92 from bregma, containing the VTA and mammillary bodies (MB), using a vibratome. Sections, distributed in eight parallel series, were stored in 0.05% azide in PB at 4 °C and processed for CB₂r, D1 and D2 dopamine receptors (D1Dr and D2Dr, respectively), mature neurons neuronal nuclei (NeuN), and astrocyte's glial fibrillary acidic protein (GFAP) immunohistochemistry using combined double fluorescent labeling. Sections were blocked in 3% horse serum, 10% goat serum, and 3% Triton X-100 in PBS (PB saline), and then incubated overnight at 4 °C with rabbit anti-CB₂r (1:500, Cayman Chemical, MI) combined with the following monoclonal antibodies: either anti-NeuN (1:400, Millipore, Temecula, CA) or anti-GFAP (1:1000, Millipore), or anti-D1Dr or anti-D2Dr (both 1:250, Santa Cruz Biotechnology, Santa Cruz, CA). In addition, other set of sections were incubated with rabbit anti-GFAP (1:1000; Sigma-Aldrich, Saint Louis, MO) combined with either mouse anti-D1Dr or anti-D2Dr. All sections were then incubated with horse biotinylated anti-mouse antibody (1:150, Vector, Burlingame, CA) and avidin-BODIPY FL (1 mg/ml, Molecular Probes, Eugene, OR) and with goat rhodamine red-X anti-rabbit (1:150, Molecular Probes). For each combination of two antibodies, the sections containing the NAcc and the VTA-MB from WT and CB₂xP mice were processed in parallel. Fluorescent sections were mounted using ProLong Gold (Molecular Probes), studied in a Leica confocal laser fluorescence microscope, and processed using the LCS Lite software.

In Vivo Microdialysis

Details of the surgical procedure and HPLC conditions are described in the Supplementary Information.

Two days after surgery, animals were habituated to the microdialysis environment overnight. The following morning, probes were perfused with a ringer solution (NaCl: 148 mM, KCl: 2.7 mM, CaCl₂: 1.2 mM, and MgCl₂: 0.8 mM, pH 6.0) at a constant rate of 1 µl/min, and a period of 1-h was allowed for stabilization. Four baseline samples were collected in all mice before drug challenge. Subsequently, mice were divided into four treatment groups as follows: Group 1 (WT saline) and group 2 (CB₂xP saline) received two injections of saline (1 every 80 min), whereas group 3 (WT cocaine) and group 4 (CB₂xP cocaine) received a first injection of saline followed by a second injection of cocaine (15 mg/kg, i.p.), and four samples were collected after each administration. Dialysates (20 µl) were injected without any purification into a HPLC system that consisted of a pump linked to an automatic injector (Agilent 1100, Palo Alto, USA), a reverse-phase column (Zorbax SB C18, 5 mm, 150 × 4.6 mm, Agilent Technologies), and a coulometric detector (Coulochem II, ESA, Chelmsford, USA) with a 5011A analytical cell. DA was quantified as previously described (Robledo *et al*, 2004). At the end of the experiments, mice were killed and the brains were coronally cut using a cryostat. Serial sections (20 µm) were stained with cresyl violet (Sigma-Aldrich, Madrid, Spain). Only those mice with correct probe placements were used in the study.

Gene Expression Analyses Real time PCR

Mice used in the motor sensitization experiment were killed 150 min after the cocaine or saline challenge. Brain slices (500 μ m) were obtained in a cryostat (-10°C) at different levels (Paxinos and Franklin, 2001) containing the regions of interest and were stored at -80°C . From these slices, the regions were dissected out as described elsewhere (Palkovits, 1983). Total RNA was isolated from the brain tissue micropunches using TRI Reagent (Ambion) and subsequently retrotranscribed to cDNA. Quantitative analysis of the relative abundance of TH, DAT, CB₁r, and μ -opioid receptor gene expressions was performed on the Step One Real Time PCR System (Applied Biosystems) according to the manufacturer's protocol. The reference gene used was 18S rRNA, detected using Taqman ribosomal RNA control reagents. Data for each target gene were normalized to the endogenous reference gene and the fold change in target gene mRNA abundance was determined using the $2^{(-\Delta\Delta\text{Ct})}$ method (Livak and Schmittgen, 2001).

Statistical Analyses

Statistical analyses were performed using Student's *t*-test by comparing two groups and one-, two-, or three-way analyses of variance (ANOVA) when comparing three or more groups. When appropriate, *post-hoc* individual differences between groups were determined using the Newman-Keuls test. Specific statistical analyses of the microdialysis study are described in Supplementary Information. Differences were considered significant when $P < 0.05$. SigmaStat v3.11 and SPSS v17 software were used for statistical analyses.

RESULTS

Motor Activity in Naïve CB₂xP and WT Mice: Cocaine Dose-Response Study

No significant differences (NS) were found in motor activity between genotypes, during the 20-min baseline session

(Figure 1a, Student's *t*-test, NS). The dose-response analysis (two-way ANOVA, Figure 1b) showed significant main effects of genotype ($F_{(1,47)} = 5.073$; $P < 0.05$), treatment ($F_{(3,47)} = 88.845$; $P < 0.001$), and a significant interaction between genotype and treatment ($F_{(3,47)} = 3.134$; $P < 0.05$). In both genotypes, cocaine significantly increased motor activity in a dose-dependent manner for 10 and 20 mg/kg (Student Newman-Keuls, $P < 0.05$), whereas 40 mg/kg showed a similar response to 20 mg/kg. However, in CB₂xP mice the increase in motor activity induced by 10 and 20 mg/kg of cocaine was significantly lower than the response observed in WT mice (Student Newman-Keuls, $P < 0.05$).

Sensitization to Motor Response Induced by Cocaine in CB₂xP and WT Mice: Effect of Challenge with Cocaine After 6 days of Withdrawal

The sensitization protocol induced a dose-related enhancement in cocaine-induced motor activity, when compared with saline treatment. However, CB₂xP mice showed significantly less sensitization to cocaine motor effects than WT mice (Figure 2a). Two-way ANOVA with repeated measures showed significant main effects of genotype ($F_{(1,106)} = 96.033$; $P < 0.001$), treatment ($F_{(2,106)} = 742.158$; $P < 0.001$) and time ($F_{(1,106)} = 32.206$; $P < 0.001$), and significant interactions genotype $\times$ treatment ($F_{(2,106)} = 46.845$; $P < 0.001$) and time $\times$ treatment ($F_{(2,106)} = 20.449$; $P < 0.001$). No significant interactions were observed between time $\times$ genotype ($F_{(1,106)} = 1.413$; NS) or between time $\times$ genotype $\times$ treatment ($F_{(2,106)} = 2.199$; NS).

A three-way ANOVA was carried out to analyze the effect of cocaine challenge after 6 days of withdrawal (Figure 2b). Significant main effects of genotype ($F_{(1,98)} = 63.443$; $P < 0.001$), pre-treatment ($F_{(2,98)} = 50.936$; $P < 0.001$), and challenge dose ($F_{(2,98)} = 187.725$; $P < 0.001$) were revealed, and significant interactions between genotype $\times$ challenge dose ($F_{(2,98)} = 15.902$; $P < 0.001$) and pre-treatment $\times$ challenge dose ($F_{(2,98)} = 8.906$; $P < 0.001$). No significant interactions were observed between genotype $\times$ pre-treatment ($F_{(2,98)} = 0.926$; NS) or between genotype $\times$ pre-treatment $\times$ challenge dose ($F_{(2,98)} = 0.496$; NS). Thus,

Figure 1 Motor activity in naïve animals and cocaine dose-response study in wild-type (WT) and CB₂r overexpressing (CB₂xP) mice. (a) Columns represent the means and vertical lines + SEM of traveled distance (cm) by WT ($n = 20$) and CB₂xP ($n = 20$) mice under basal conditions. (b) Columns represent the means and vertical lines + SEM of traveled distance by WT and CB₂xP mice ($n = 6$ per group) in the open-field test during 20-min, 10-min after cocaine (10, 20, and 40 mg/kg) or saline administration. * $P < 0.05$ vs WT mice receiving the same treatment. # $P < 0.05$ vs saline-treated mice of similar genotype.

in saline pre-treated mice both doses of cocaine increased motor behavior compared with the saline challenge, but this effect was significantly lower in the CB₂xP mice as compared with the WT mice. In cocaine pre-treated mice, the cocaine challenge induced a dose-related increase in traveled distance compared with the saline challenge in WT mice. However, in CB₂xP mice only the dose of 20 mg/kg increased locomotion compared with saline. Differences between genotypes were observed and CB₂xP mice displayed a significantly lower motor response than that observed in WT mice (Figure 2b).

Cocaine Conditioned Place Preference

During the pre-conditioning period (phase I), no difference was observed in the time spent in the two compartments by both genotypes (Student's *t*-test; NS). These results ruled out the possibility of initial unconditioned preference for either of the two compartments by any of the genotypes. Interestingly, on the test day (phase III), after the

conditioning period (phase II), the WT mice did not present a clear CPP for the conditioning compartment, whereas the CB₂xP mice showed conditioned place aversion. The CB₂xP mice spent significantly less time (22%) in the cocaine-conditioned compartment compared with WT mice (Figure 3, Student's *t*-test, $t = 3.707$, 14 df; $P < 0.05$).

Cocaine Self-Administration

Acquisition of cocaine self-administration in CB₂xP and WT mice. CB₂xP mice self-administer less cocaine than WT mice along the different training sessions (Figure 4a). A clear discrimination between the active and the inactive holes was observed for WT mice during the acquisition of operant responding for cocaine (0.5 mg/kg/infusion; see Supplementary Information Figure S1A). Mean time to achieve the acquisition criteria for WT mice was 5.0 ± 0.68 days, and 100% of the animals reached the acquisition criteria at day 10. CB₂xP mice trained to self-administer cocaine started to discriminate between the active and the inactive holes on the fourth training session, and discrimination was maintained from the sixth session until the last session (see Supplementary Information Figure S1B). One-way ANOVAs were performed comparing genotypes in the active and inactive (see Supplementary Figure S2A) holes for each of the training sessions (see Table 1 for significance values) and comparing active and inactive holes on each of the training sessions for WT and CB₂xP mice (see Table 2 for significance values). Mean time to achieve the acquisition criteria for CB₂xP mice was 7.85 ± 1.03 days, and 40% of the animals reached the acquisition criteria at day 10. However, the motivation to obtain cocaine in mice achieving the acquisition criteria was similar in both genotypes (Figure 4b). Thus, one-way ANOVA showed no differences between genotypes in the breaking point achieved during the PR schedule of reinforcement. These results suggest a reduction of cocaine reinforcing effects in CB₂xP mice when compared with WT controls.

Extinction of cocaine self-administration and cue-induced relapse of cocaine-seeking behavior in CB₂xP and WT mice. Following PR schedule of reinforcement mice underwent extinction sessions until <30% of the

Figure 2 Sensitization to motor response induced by cocaine in wild-type (WT) and CB₂r overexpressing (CB₂xP) mice: Effect of challenge with cocaine after 6 days of withdrawal. Mice received a daily cocaine dose 10–20 mg/kg or saline, during 20 days. (a) Columns represent the means and vertical lines + SEM of traveled distance (cm) by mice, on day 1, 10, and 20 of cocaine or saline treatment. * $P < 0.001$ vs WT mice, # $P < 0.001$ vs day 1, & $P < 0.001$ vs saline, and \$ $P < 0.001$ vs cocaine (10 mg/kg). After 6 days of withdrawal from 20 days of cocaine (10 or 20 mg/kg) or saline pretreatment, both genotypes were challenged with a single dose of cocaine (10 or 20 mg/kg) or saline; ($n = 7$ mice per group). mean response on the active hole (during acquisition) was observed (Figure 4c; see Supplementary Figure S2B for operant response in the inactive hole). Mice achieving the criteria for extinction underwent a reinstatement session evaluating cue-induced relapse to cocaine-seeking behavior (Figure 4d). No apparent differences between genotypes in the extinction process or in the capacity of cue to induce reinstatement of cocaine-seeking behavior were observed (see ANOVAs analyses in Supplementary Information).

Water maintained self-administration in CB₂xP and WT mice. Additional CB₂xP and WT mice were trained to self-administer water under a FR1 schedule of reinforcement (Figure 5a). WT animals started to discriminate between the active and the inactive holes from the third training session (data not shown) and the discrimination was maintained during the next seven sessions. The stability criteria were achieved by 86% of the animals tested and the mean time required to reach it at this group was 4.83 ± 0.90

Figure 5 Acquisition of operant responding for water in wild-type (WT) and CB₂r overexpressing (CB₂xP) mice. (a) Average number of nose-pokes + SEM in the active hole in both WT (empty circles) and CB₂xP (filled circles) mice in 1-h sessions during 10 days of training with water under a fixed ratio 1 (FR1) schedule of reinforcement (10 µl of water in 10 s.); WT (*n* = 7), CB₂xP (*n* = 8). (b) Breaking point achieved by WT (white bar) and CB₂xP (black bar) mice under a progressive ratio schedule of reinforcement; WT (*n* = 6), CB₂xP (*n* = 8).

days. CB₂xP mice also showed discrimination from the third until the last training session. In this group, the stability criterion was achieved by all the animals tested and the mean time required to reach it was of 4.12 ± 0.81 days. One-way ANOVA showed no significant differences between CB₂xP and WT control mice in the number of drinks self-administrated on any training day (see Table 3 for significance values and Supplementary Figure S2C).

In order to evaluate whether WT and CB₂xP presented differences in the motivation to obtain water, mice achieving the acquisition criteria underwent a PR schedule of reinforcement. No differences between genotypes were observed in the breaking point achieved under the PR schedule (Figure 5b). These results show that the reinforcing effects of the natural reinforcer (water) were not modified in CB₂xP mice, and the capacity of these mice to acquire an operant responding also remained unaltered.

Phenotypical Characterization of NAcc and VTA Cells

In WT and CB₂xP mice, cells double immunolabeled with CB₂r-NeuN (Figure 6a–f) and CB₂r-GFAP (Figure 6g–l) antibodies were seen in several regions of the mice brain, and in particular in the NAcc and VTA, which indicates that both neurons and astrocytes are CB₂r immunoreactive (i.r.) in these areas. All neurons were CB₂r i.r. but a few of GFAP i.r. astrocytes were not labeled with CB₂r antibodies. CB₂r immunolabeling was found in the soma of the neuron and in the surrounding neuropile (Figure 6a–f), whereas it was observed in the soma and processes of the astrocytes (Figure 6g–l).

D1Dr i.r. cells were seen in several brain regions in both WT and CB₂xP mice. However, no D1Dr i.r. cells were seen in the NAcc and VTA in WT or in CB₂xP mice (Figure 7a–c). For instance, in the hippocampal dentate gyrus (Figure 7g–i), some cells were D1Dr i.r. and a fraction of these were also CB₂r i.r. D2Dr i.r. cells were seen in the NAcc and VTA, which were also CB₂r i.r. (Figure 7d–f). However, immunolabeling of these cells in the NAcc and VTA (Figure 7a–f and Supplementary Figure S3) was weaker than that of cells located in other brain areas such as the cortex and MB

(Figure 7j–l). In all cases, both D1Dr i.r. and D2Dr i.r. cells remained unlabeled with anti-GFAP antibodies suggesting that they were neurons (Supplementary Figure S3).

In Vivo Microdialysis

Histological analysis of the brains showed that all the animals included in the experiment had microdialysis probes placed correctly in the NAcc (between +1.10 mm. and +1.78 mm anterior to bregma; Figure 8a).

No significant differences in basal extracellular DA levels in the NAcc were observed between genotypes (mean of four baseline samples: WT: 4.32 ± 1.04 pg/20 µl; CB₂xP: 4.94 ± 0.94 pg/20 µl; Figure 8b). Two-way repeated measures ANOVA revealed a significant main effect of time ($F_{(3,72)} = 2.910$; $P < 0.05$), but no significant effect of the treatment group was observed ($F_{(3,24)} = 1.627$; NS), and no significant interaction between factors ($F_{(9,72)} = 1.848$; NS) was found. Following saline administration, no significant differences in DA outflow were observed between treatment groups. Two-way repeated measures ANOVA revealed

Figure 6 Immunolabeling for CB₂ receptors (CB₂r) and neuronal nuclei (NeuN) in the ventral tegmental area (VTA) and the nucleus accumbens (NAcc) and for CB₂r and glial fibrillary acidic protein (GFAP) in the VTA of wild-type (WT) and CB₂r overexpressing (CB₂xP) mice. Confocal photomicrographs showing immunolabeling for CB₂r (red cells in (a) and (d)) and NeuN (green cells in (b) and (e)) in the VTA of WT and the NAcc of CB₂xP mice. Double labeling (yellow cells in (c) and (f)) both in the VTA and the NAcc indicates that most of the CB₂r immunoreactive (i.r.) cells are neurons. A CB₂r cell not labeled for NeuN is shown in (c) (arrow). (g–l) Immunolabeling for CB₂r (red cells in (g) and (j)) and GFAP (green cells in (h) and (k)) in the VTA of WT and CB₂xP mice. Double labeling (yellow cells in (i) and (l)) shows that most of the GFAP i.r. astrocytes are also immunolabeled for CB₂r (arrows in (i) and (l)). GFAP i.r. astrocytes not CB₂r i.r. can be rarely seen (arrow head). CB₂r immunolabeled cells, most probably neurons, are showed in (i) and (l) (double arrow). Same scale for (b–l).

non-significant main effects of time ($F_{(3,72)} = 1.098$; NS) or treatment group ($F_{(3,24)} = 0.039$; NS), and no interaction between factors ($F_{(9,72)} = 1.942$; NS; Figure 8b). Following the cocaine challenge, two-way repeated measures ANOVA revealed significant main effects of time ($F_{(3,72)} = 16.953$; $P < 0.001$) and treatment group ($F_{(3,24)} = 6.639$; $P < 0.01$), and a significant interaction between factors ($F_{(9,72)} = 6.021$;

$P < 0.001$). Subsequent *post-hoc* tests revealed that the challenge administration of cocaine at 15 mg/kg increased DA levels in the NAcc compare with saline administration in WT and CB₂xP mice (WT: $P < 0.05$; CB₂xP: $P < 0.01$), but this increase was not significantly different between genotypes (WT cocaine vs CB₂xP cocaine: $P > 0.05$; Figure 8b).

Figure 7 Immunolabeling for CB₂ receptors (CB₂r), D1 and D2 dopamine receptors (D1Dr and D2Dr, respectively) in wild-type (WT) and CB₂r overexpressing (CB₂xP) mice. Confocal photomicrographs showing immunolabeling for CB₂r (red cells in (a), (d), (g) and (j)), and D1Dr and D2Dr (green cells in (b), (e), (h) and (k)) in the ventral tegmental area (VTA) of WT mice (a–f), hippocampal dentate gyrus (DG; g–i) and mammillary bodies (MB; j–l) of CB₂xP mice. Double labeling (yellow cells) is shown in (c), (f), (i), and (l). In the VTA and the NAcc no D1Dr immunoreactive (i.r.) cells were seen, but they were more numerous in other brain areas. Several D1Dr i.r. neurons in the granular layer (arrow) and hilus of the dentate gyrus of the hippocampus are shown; some of them are also CB₂r i.r. (yellow labeling in (i)). Neurons double labeled for CB₂r and D2Dr in the MB are shown (l). Note that most of the D2Dr i.r. are also labeled for CB₂r. Same scale for (b–l).

Changes in TH and DAT Gene Expression Induced by Cocaine in the VTA of CB₂xP and WT Mice

The results showed increased baseline TH gene expression in the VTA of CB₂xP compared with WT mice (Figure 9a, Student's *t*-test, $t = -3.551$, 12 df; $P < 0.05$). After the saline or cocaine challenge, the three-way ANOVA revealed significant main effects of genotype ($F_{(1,70)} = 17.760$;

$P < 0.001$), pre-treatment ($F_{(2,70)} = 12.716$; $P < 0.001$), and challenge dose ($F_{(2,70)} = 106.267$; $P < 0.001$; Figure 9b). Significant interactions between genotype $\times$ pre-treatment ($F_{(2,70)} = 15.142$; $P < 0.001$), genotype $\times$ challenge dose ($F_{(2,70)} = 18.430$; $P < 0.001$), pre-treatment $\times$ challenge dose ($F_{(2,70)} = 5.574$; $P < 0.01$), and genotype $\times$ pre-treatment $\times$ challenge dose ($F_{(2,70)} = 3.882$; $P < 0.05$) were found. CB₂xP mice pre-treated with saline showed increased TH gene

Figure 8 Microdialysis data for wild-type (WT) and CB₂r overexpressing (CB₂xP) mice. (a) A coronal section of the brain of a representative mouse stained with cresyl violet (magnification: $\times 2.0$) showing the position of the microdialysis probe in the NAcc. (b) Dopamine (DA) outflow in the NAcc (% of baseline + SEM) during 240 min before and after drug challenge (arrows) in four treatment groups: Group 1 (WT saline (sal)) and group 2 (CB₂xP saline) received two injections of saline (one every 80 min), group 3 (WT cocaine (coc)) and group 4 (CB₂xP cocaine) received a first injection of saline followed by a second injection of cocaine (15 mg/kg, i.p.), and four dialysates (20 μ l) were collected after each administration. ** $P < 0.01$ (CB₂xP cocaine vs CB₂xP saline), + $P < 0.05$ (WT cocaine vs WT saline).

expression compared with WT mice, supporting baseline differences between the two genotypes.

The effect of both cocaine pre-treatment and challenge reduced TH gene expression in CB₂xP and WT mice ($P < 0.001$). In animals pre-treated with 20 mg/kg of cocaine there was significantly reduced TH gene expression compared with those pre-treated with 10 mg/kg of cocaine or saline ($P < 0.05$). On the other hand, cocaine challenge induced a dose-related significant reduction of TH gene expression compared with saline challenged mice ($P < 0.05$). In contrast, CB₂xP mice pre-treated with 20 mg/kg of cocaine and challenged with saline exhibited significantly increased TH gene expression compared with WT mice receiving the same treatment. This difference was not observed with the cocaine challenge (20 mg/kg).

Baseline DAT gene expression was significantly increased in CB₂xP compared with WT mice (Figure 9c, Student's t -test, $t = -2.967$, 11 df; $P < 0.05$). The three-way ANOVA revealed significant changes in DAT gene expression after cocaine or saline challenge due to genotype ($F_{(1,70)} = 79.621$; $P < 0.001$), pre-treatment ($F_{(2,70)} = 10.127$; $P < 0.001$), and challenge dose ($F_{(2,70)} = 5.875$; $P < 0.005$; Figure 9d). Significant interaction between genotype $\times$ pre-treatment ($F_{(2,70)} = 4.965$; $P < 0.05$) was found, whereas genotype $\times$ challenge dose ($F_{(2,70)} = 1.744$; NS), pre-treatment $\times$ challenge dose ($F_{(2,70)} = 0.889$; NS), and genotype $\times$ pre-treatment $\times$ challenge dose ($F_{(2,70)} = 1.709$; NS) were not

significant. Regarding genotype, these results confirmed baseline differences between CB₂xP and WT mice. The effect of cocaine pre-treatment (10 and 20 mg/kg reduced gene expression of DAT compared with saline pre-treatment in WT mice ($P < 0.05$). Moreover, the decrease of DAT gene expression induced by cocaine challenge in cocaine pre-treated mice was 50% lower in CB₂xP compared with WT mice.

Changes in μ -Opioid and CB₁r Gene Expression Induced by Cocaine in the NAcc of CB₂xP and WT Mice

CB₂xP mice presented decreased baseline μ -opioid receptor gene expression compared with WT mice (Figure 10a, Student's t -test, $t = 3.005$, 13 df; $P < 0.001$). The three-way ANOVA revealed significant changes in μ -opioid receptor gene expression after cocaine or saline challenge due to genotype ($F_{(1,70)} = 12.930$; $P < 0.005$), pre-treatment ($F_{(2,70)} = 44.926$; $P < 0.001$), and challenge dose ($F_{(2,70)} = 19.386$; $P < 0.001$; Figure 10b). Significant interactions between pre-treatment $\times$ challenge dose ($F_{(2,70)} = 39.075$; $P < 0.001$) and genotype $\times$ pre-treatment $\times$ challenge dose ($F_{(2,70)} = 3.788$; $P < 0.05$) were found, whereas genotype $\times$ pre-treatment ($F_{(2,70)} = 0.320$; NS) and genotype $\times$ challenge dose ($F_{(2,70)} = 1.719$; NS) were not significant. Regarding genotype, these results confirmed baseline differences between CB₂xP and WT mice. Cocaine pre-treatment reduced μ -opioid receptor gene expression in CB₂xP and WT mice ($P < 0.001$). Animals pre-treated with 10 and 20 mg/kg of cocaine presented a significant reduction compared with those pre-treated with saline ($P < 0.05$). On the other hand, depending on pre-treatment received, cocaine challenge (20 mg/kg) induced a different effect on μ -opioid receptor gene expression compared with cocaine (10 mg/kg) and saline challenged mice (Figure 10b). Thus, in saline pre-treated mice, a cocaine challenge (20 mg/kg) significantly increased μ -opioid receptor gene expression ($P < 0.05$). In contrast, the challenge with cocaine significantly decreased μ -opioid receptor gene expression ($P < 0.05$) in mice pre-treated with cocaine.

On the other hand, under baseline conditions no differences were found in CB₁r gene expression between CB₂xP and WT mice (Figure 10c, Student's t -test; NS). The three-way ANOVA revealed significant changes in CB₁r gene expression after cocaine or saline challenge due to pre-treatment ($F_{(2,70)} = 38.303$; $P < 0.001$) and challenge dose ($F_{(2,70)} = 13.423$; $P < 0.001$), whereas genotype ($F_{(1,70)} = 0.271$; NS) was not significant (Figure 10d). Significant interactions between genotype $\times$ pre-treatment ($F_{(2,70)} = 19.719$; $P < 0.001$), genotype $\times$ challenge dose ($F_{(2,70)} = 6.526$; $P < 0.005$), pre-treatment $\times$ challenge dose ($F_{(2,70)} = 28.894$; $P < 0.001$), and genotype $\times$ pre-treatment $\times$ challenge dose ($F_{(2,70)} = 7.232$; $P < 0.005$) were found. Regarding genotype, these results confirmed the lack of significant differences in baseline CB₁r gene expression between CB₂xP and WT mice. The effect of both cocaine pre-treatment and challenge reduced the expression of CB₁r gene in CB₂xP and WT mice ($P < 0.001$). Thus, animals pre-treated with cocaine presented a dose-related significant reduction compared with those pre-treated with saline ($P < 0.05$). On the other hand, cocaine challenge (10 and 20 mg/kg) induced a significant reduction of CB₁r gene

Figure 9 Changes in tyrosine hydroxylase (TH) and DA transporter (DAT) gene expression induced by cocaine in the ventral tegmental area (VTA) of CB₂r overexpressing (CB₂xP) and wild-type (WT) mice. (a, c) Columns represent the means and vertical lines + SEM of 2^{-ΔΔCt} of relative TH and DAT gene expression, respectively, in WT (*n* = 6) and CB₂xP (*n* = 6) mice measured in the VTA under baseline conditions. (b, d) WT and CB₂xP mice (*n* = 6 per group) received a challenge of saline or cocaine (10–20 mg/kg) after 6 days of withdrawal from 20 days of pre-treatment with saline or cocaine (10–20 mg/kg). Columns represent the means and vertical lines + SEM of 2^{-ΔΔCt} of relative TH and DAT gene expression in WT and CB₂xP mice challenged with saline or cocaine. **P* < 0.001 vs WT, &*P* < 0.05 vs saline challenge, •*P* < 0.05 vs cocaine challenge (10 mg/kg), \$*P* < 0.05 vs saline pre-treatment and, +*P* < 0.05 vs cocaine pre-treatment (10 mg/kg).

Figure 10 Changes in μ-opioid and CB₁ receptor gene expression induced by cocaine in the nucleus accumbens (NAcc) of CB₂r overexpressing (CB₂xP) and wild-type (WT) mice. (a, c) Columns represent the means and vertical lines + SEM of 2^{-ΔΔCt} of relative μ-opioid and CB₁ receptor gene expression, respectively, in WT and CB₂xP mice (*n* = 6 per group) measured in the NAcc under baseline conditions. (b, d) WT and CB₂xP mice (*n* = 6 per group) received a challenge of saline or cocaine (10–20 mg/kg) after 6 days of withdrawal from 20 days of pre-treatment with saline or cocaine (10–20 mg/kg). Columns represent the means and vertical lines + SEM of 2^{-ΔΔCt} of relative μ-opioid and CB₁ receptor gene expression in WT and CB₂xP mice challenged with saline or cocaine. **P* < 0.001 vs WT, &*P* < 0.05 vs saline challenge, \$*P* < 0.05 vs saline pre-treatment and, +*P* < 0.05 vs cocaine pre-treatment (10 mg/kg).

expression compared with saline challenge (*P* < 0.05; Figure 10d). There were different effects of the combination of pre-treatment and challenge dose (*P* < 0.001), and the

interaction of these factors with genotype resulted statistically significant (*P* < 0.005). Thus, in saline pre-treated mice, cocaine challenge decreased less CB₁r gene expression

in CB₂xP compared with WT mice. In contrast, cocaine challenge decreased more CB₁r gene expression in cocaine pre-treated CB₂xP mice compared with WT mice.

DISCUSSION

The present results provide evidence for the relevant role of the cannabinoid CB₂r in the development of motor sensitization and the reinforcing effects of cocaine. This is supported by several observations: (a) CB₂xP mice showed reduced motor response to acute cocaine (10–20 mg/kg) compared with WT mice; (b) motor sensitization induced by chronic cocaine administration was reduced in CB₂xP mice; (c) CB₂xP mice presented cocaine-induced conditioned place aversion; (d) cocaine self-administration was reduced in CB₂xP mice; (e) CB₂xP mice presented increased TH (60%) and DAT (88%) in the VTA and decreased μ -opioid receptor (25%) gene expression in the NAcc; and (f) the decrease in DAT gene expression in the VTA induced by a cocaine challenge in cocaine-sensitized mice was 50% lower in CB₂xP compared with WT mice.

CB₂xP and WT mice showed similar spontaneous motor activity. This finding was consistent with a previous study from our laboratory (Garcia-Gutierrez and Manzanares, 2011). The acute administration of cocaine enhanced the motor activity in both genotypes, although the response in CB₂xP mice was significantly less pronounced. These attenuated motor effects were significant only with 10 and 20 mg/kg of cocaine, whereas the higher dose of cocaine (40 mg/kg) did not produce significant differences between genotypes. The changes found in TH and DAT gene expression could explain the different response to cocaine (10–20 mg/kg), however, it is possible that the elevated cocaine dose (40 mg/kg) induced a ceiling effect that precluded discriminating between both genotypes. On the other hand, we recently reported that deletion of CB₂r increased the sensitivity to the motor responses of an acute dose of cocaine in the open field (Ortega-Alvaro *et al*, 2011).

Repeated exposure to psychostimulants produces sensitization, revealed by progressive enhancement of their hyperlocomotor effects (Robinson and Berridge, 1993, 2001). This motor sensitization remains after the withdrawal of the chronic psychostimulant treatment (Pierce and Kalivas, 1997). During the development of cocaine-induced motor sensitization, CB₂xP mice showed less hyperlocomotion than WT mice, specifically at the dose of 20 mg/kg, where differences between genotypes were statistically significant. These results point to the involvement of CB₂r in the development of cocaine-induced motor sensitization in mice. Nevertheless, on days 1 and 20 of the sensitization protocol, 10 mg/kg of cocaine did not produce statistically significant differences in motor activity between genotypes, contrary to what was observed in the dose-response study. The discrepancies found in this cocaine-induced motor response may be due to the limiting dose factor together with the specific features of the sensitization protocol. On day 0, mice were habituated to the open field cage for a 20-min period without treatment. This habituation process was not carried out in the dose-response study. Thus, the cocaine dose-response results are not comparable to the results of cocaine sensitization on days 1 and 10. On

the other hand, the challenge with cocaine at the high dose (20 mg/kg) markedly increased motor activity in cocaine pre-treated WT mice compared with saline pre-treated controls, whereas in CB₂xP mice this effect was significantly lower. Thus, the expression of cocaine-induced sensitization may also be modulated by CB₂r in mice.

The specific molecular mechanisms by which the overexpression of CB₂r resulted in decreased cocaine-induced motor response and sensitization remain to be determined. The CB₂r has been identified in the brain areas regulating motor functions such as caudate-putamen and substantia nigra (Garcia-Gutierrez *et al*, 2010; Gong *et al*, 2006), and alterations in dopaminergic and glutamatergic transmission have been closely related with the development of cocaine behavioral sensitization (Vanderschuren and Kalivas, 2000). Thus, it may be possible that the increased expression of CB₂r in these brain areas resulted in alterations of the activity of these neurotransmitter systems decreasing motor responses to cocaine. In agreement, in this study specific changes in DAT and TH gene expression, key components of dopaminergic transmission, were found in CB₂xP compared with WT mice. The gene expression of TH and DAT in the VTA were measured in both genotypes, under baseline conditions and following cocaine or saline challenge after 6 days of withdrawal from saline or cocaine chronic treatment. The acute cocaine administration in saline pre-treated groups will help to differentiate the changes in gene expression due to neuroadaptations after chronic cocaine treatment from those produced by a single cocaine injection in saline pre-treated animals. The results revealed that CB₂xP mice presented higher TH (60%) and DAT (89%) gene expressions than WT mice under baseline conditions. Acute cocaine administration in saline or cocaine pre-treated mice similarly decreased TH gene expression in both genotypes. On the other hand, the significant reduction in DAT gene expression occurring in cocaine pre-treated mice was less pronounced (~50%) in CB₂xP than in WT mice, indicating that chronic administration of a high dose of cocaine induces less adaptive changes in DAT gene expression in the VTA of CB₂xP than WT mice. As DAT deletion facilitates cocaine-induced sensitization (Morice *et al*, 2010), the enhanced DAT gene expression found in transgenic mice might act in an opposite manner, interfering on cocaine-induced sensitization.

CB₂xP mice presented lower (25%) μ -opioid receptor gene expression than WT mice under baseline conditions in the NAcc. The cocaine challenge increased μ -opioid receptor gene expression in the NAcc of saline pre-treated mice whereas it decreased the same in cocaine pre-treated mice. These changes occurred in a similar manner in both genotypes. These results suggest that the overexpression of CB₂r has no consequences on cocaine-induced regulation of μ -opioid receptors in the NAcc, although both genotypes presented differences in the μ -opioid receptor baseline levels. On the other hand, CB₁r gene expression in the NAcc under baseline conditions was similar in both genotypes. Cocaine challenge in WT mice pre-treated with saline significantly decreased CB₁r gene expression, whereas this effect was not observed in CB₂xP mice. In contrast, the cocaine challenge in cocaine pre-treated mice significantly decreased CB₁r gene expression in CB₂xP but not in WT

mice. These results suggest that the pattern of cocaine administration (acute or chronic) differently affected CB₁r gene expression in CB₂xP and WT mice. This fact might be due to potential compensatory mechanisms between CB₁r and CB₂r.

This study demonstrates the involvement of the cannabinoid CB₂r in the actions of cocaine in the CPP, as well as in the acquisition of intravenous cocaine self-administration. WT mice did not present a clear CPP for the conditioning compartment, whereas CB₂xP mice showed cocaine-induced conditioned place aversion. The ratio of mice reaching the acquisition criteria in self-administration studies was reduced and the mean time to achieve these criteria was increased in the CB₂xP group. An increased baseline gene expression of TH and DAT was revealed in CB₂xP mice and the enhanced expression of DAT was maintained even after repeated cocaine administration. The reinforcing effects of cocaine are related to its ability to inhibit DAT (Di Chiara, 1995; Koob and Bloom, 1988; Kuhar *et al*, 1991). The enhanced DAT gene expression might account for the decreased perception of cocaine reinforcing effects in CB₂xP mice and for the consequent impairment in the acquisition of cocaine self-administration. However, the role of DAT in cocaine reinforcing effects has also been questioned (Rocha *et al*, 1998; Sora *et al*, 2001). In spite of the decreased acquisition of cocaine self-administration in CB₂xP mice, no differences in the motivation to obtain cocaine were observed between mice of both genotypes reaching the acquisition criteria. A similar dissociation between rates of acquisition and motivation for drug self-administration has been previously reported in the mice with a different sensitivity to the reinforcing effects of the drug (Galeote *et al*, 2008; Trigo *et al*, 2009). Thus, CB₂r overexpression interferes with the acquisition of cocaine self-administration behavior under a continuous schedule of reinforcement, but once this behavior is established, CB₂r overexpression does not seem to affect performance on a progressive schedule of reinforcement, possibly suggesting that CB₂r do not critically contribute to the motivational properties of cocaine. The deficits in cocaine self-administration observed in CB₂xP mice cannot be attributed to possible unspecific learning or motor deficits produced by the CB₂r overexpression as both genotypes similarly acquired and maintained stable operant responding for water.

It has been recently reported (Xi *et al*, 2011) that pharmacological activation of CB₂r attenuated the effects of cocaine on the enhancement of extracellular DA levels in the NAcc of WT mice. In the same study, blockade of CB₂r elevated basal extracellular DA levels in the NAcc, whereas deletion of CB₂r did not alter this measure. Our *in vivo* microdialysis studies did not reveal differences between genotypes with respect to basal DA extracellular levels in the NAcc or after acute cocaine administration at 15 mg/kg. WT mice treated with CB₂r agonists are not necessarily equivalent to mice overexpressing CB₂r from the behavioral and neurochemical point of view. Indeed, the dose and duration of the pharmacological treatment may produce adaptive changes in the number and/or functional activity of the CB₂r that could explain, at least in part, the neurochemical and behavioral responses. Besides, the genetic manipulation of the receptor may affect other

neurochemical systems coupled with CB₂r function in a different manner than the administration of the cannabinoid agonist in WT mice. In this respect, we have previously reported increased GABA α_2 and GABA γ_2 gene expression in the hippocampus and amygdala of CB₂xP mice (Garcia-Gutierrez and Manzanares, 2011). This enhancement of the GABAergic function could also regulate differently the cocaine-induced behaviors in CB₂xP compared with WT mice.

The results of this study also revealed that CB₂r are found in neurons and astrocytes in both genotypes. In addition, D2Dr i.r. cells were seen in the NAcc and VTA, which were also CB₂r i.r. in both WT and CB₂xP mice. These findings suggest that CB₂r and D2Dr are located in the same neurons of the NAcc and VTA. There is no information available regarding the functional cooperation between the CB₂r and D2Dr. However, an interaction between 2-arachidonoylglycerol and DA receptors has been described in rat NAcc core neurons mediating an enhancement of firing (Seif *et al*, 2011). Taken together, these results might provide a cellular mechanism to understand the important role of NAcc D2Dr and CB₂r in the behavioral responses associated to the acquisition of drug-seeking behavior. Moreover, DA modulation of excitatory currents in the striatum controlled by the expression of D1Dr or D2Dr is modified by endocannabinoids (Andre *et al*, 2010), suggesting that activation of postsynaptic DA receptors controls endocannabinoid mobilization. The precise molecular mechanisms by which the CB₂r may interact with the D2Dr remain to be determined.

In conclusion, the results presented here demonstrate that overexpression of CB₂r reduced the effects of cocaine on motor sensitization, CPP and self-administration. Changes in DAT, TH, and μ -opioid receptor gene expression were found in the VTA or NAcc of CB₂xP mice that may be involved, at least in part, in these distinct behavioral responses to cocaine. The results point out that pharmacological manipulation of the CB₂r might be considered a new valuable target for the treatment of cocaine dependence. Further studies are needed to explore these hypotheses.

ACKNOWLEDGEMENTS

This research was supported by 'Instituto de Salud Carlos III' (RETICS, RD06/0001/1004), 'Plan Nacional Sobre Drogas' (PNSD 2007/061), Fundación para la Investigación en Salud Castilla La Mancha, FISCAM), and 'Ministerio de Ciencia e Innovación' (#SAF 2008-01106 and #SAF 2011-23420) to JM; by 'Instituto de Salud Carlos III' (RETICS, RD06/001/001), 'Ministerio de Ciencia e Innovación' (#SAF2007-64062), and Generalitat de Catalunya (#2009SGR00731 and the ICREA Academia award) to RM; and by the 'Ministerio de Ciencia e Innovación' (#SAF2009-10689) to PB Postdoctoral fellows AO-A and AT are supported by FISCAM, and JMT by 'Becas para estancias cortas de especialización e investigación en psiquiatría y psicología de la infancia y adolescencia o en neurociencias' Fundación Alicia Koplowitz. AA-F (predoctoral fellow) and Analía Rico (AR, technician) are supported by RETICS. MSG-G is a predoctoral fellow supported by 'Ministerio de Ciencia e Innovación'.

DN is a predoctoral FPI fellow. We thank AR for his excellent technical assistance, and Dulce Real for her contribution in the microdialysis and HPLC experiments. The partial support of FEDER funds (EU) is also acknowledged.
