Cocaine dependence is characterized by compulsive drug taking and reduced involvement in social, occupational, or recreational activities. Unraveling the diverse mechanisms contributing to the loss-of-interest in these 'non-drug' pursuits is essential for understanding the neurobiology of addiction and could provide additional targets for treating addiction. The study objectives were to examine changes in cocaine-induced dopamine (DA) overflow in the nucleus accumbens (NAc) over the course of self-administration and determine the roles of α 1- and β -adrenergic receptors (AR) in the loss-of-interest in food rewards following the development of an addicted phenotype in male and female rats. Subjects were given access to cocaine and palatable food pellets in a choice self-administration paradigm to identify 'addicted' cocaine-preferring (CP) individuals and resistant pellet-preferring (PP) individuals based on their patterns of self-administration over 7 weeks. Cocaine-induced DA overflow in the NAc was examined with microdialysis early and late during self-administration (weeks 2 and 7). Subjects were treated in counter-balanced order with propranolol (β -AR antagonist), terazosin (α 1-AR antagonist), or vehicle for an additional 3 weeks of self-administration. CP rats displayed increased motivation for cocaine and attenuated motivation for pellets following the development of cocaine preferences. In females, the estrous cycle affected pellet, but not cocaine, self-administration. CP rats displayed attenuated cocaine-induced DA overflow in the NAc. Propranolol enhanced cocaine reinforcement and reduced pellet intake, whereas terazosin enhanced motivation for pellets and reversed preferences in a subset of CP rats. The implications of these results for the treatment of addiction are discussed.

Neuropsychopharmacology (2015) **40**, 2696–2704; doi:10.1038/npp.2015.116; published online 13 May 2015

INTRODUCTION

Addiction is characterized by persistent drug-seeking and use despite serious physiological, medical, and social consequences (Chen *et al*, 2011; Degenhardt and Hall, 2012; Sommers *et al*, 2006). Neurobiological addiction models primarily focus on reinforcement mechanisms and alterations in mesocorticolimbic pathways (Koob and Volkow, 2010; Volkow *et al*, 2010). However, an additional feature of addiction is reduced involvement with friends and family, jobs, and recreational activities as consequences of drug use. These secondary consequences may be particularly relevant to perpetuating the addiction cycle, as they involve the loss-of-interest in alternative pursuits/rewards that might otherwise compete with drugs and promote abstinence.

Numerous preclinical studies demonstrate that alternative rewards, including palatable food, social partners, and

running wheels, reduce drug use and seeking (Liu and Grigson, 2005; Peterson *et al*, 2014; Westenbroek *et al*, 2013). However, it is unclear whether alternative rewards promote resilience, or just unmask the fact that many individuals find drugs less rewarding than these alternatives (Lenoir *et al*, 2007; Perry *et al*, 2013). We have developed a paradigm that captures several features consistent with diagnostic criteria for addiction, including escalation of cocaine intake and reduced interest in palatable food rewards that were previously highly preferred (Perry *et al*, 2013). Thus, we can examine mechanisms contributing to the enhanced reinforcing effects of drugs and reduced involvement in alternative pursuits, and directly test whether reinvigoration of interest in alternative rewards reduces drug use.

The primary objectives of this study were to examine the contributions of dopamine (DA) and norepinephrine (NE) to cocaine preferences in male and female rats, as alterations in these monoamines underlie many aspects of addiction (Baik, 2013; Schmidt and Weinshenker, 2014). Chronic cocaine use is associated with reduced DA neurotransmission in the nucleus accumbens (NAc) and striatum in human and non-human animal models (Calipari *et al*, 2014; Gerrits *et al*, 2002; Volkow *et al*, 1997). Attenuated cocaine-induced DA in the NAc may underlie escalation of intake (Willuhn *et al*, 2014; Wise *et al*, 1995), whereas reduced basal DA may contribute to anhedonia and loss-of-interest in alternative

rewards. Therefore, we monitored changes in cocaine-induced DA overflow in the NAc across self-administration to determine whether CP rats developed this neurochemical feature of addiction.

Chronic cocaine use also enhances central noradrenergic function (Beveridge *et al*, 2005; Mash *et al*, 2005), which may contribute to the loss-of-interest in alternative rewards. Adrenergic receptors (AR) are implicated in a variety of stimulant-induced behaviors (Schmidt and Weinshenker, 2014). $\alpha 1$ -AR antagonists reduce motivation for cocaine and cocaine-induced DA overflow in the NAc (Mitrano *et al*, 2012; Wee *et al*, 2008). β -AR antagonists also reduce cocaine responding, but potentiate cocaine-induced DA in the NAc (Harris *et al*, 1996). Activation of $\alpha 1$ - or β -AR in several brain regions underlies stimulant-induced hypophagia (Leibowitz, 1975; Levone *et al*, 2015; Wellman *et al*, 2002; Wellman, 2000). Therefore, we treated animals with the $\alpha 1$ -AR antagonist (terazosin) and non-selective β -AR antagonist (propranolol) to examine effects on cocaine preferences. We predicted that terazosin would reinvigorate interest in the food reward, reduce motivation for cocaine (ostensibly by further attenuating cocaine-induced DA) and that this would shift the preferences of CP rats back to the alternative reward. We predicted that propranolol would also reduce cocaine intake (ostensibly by potentiating DA neurotransmission). However, β -blockade can also increase NE overflow and preferential $\alpha 1$ -AR activation (Tuross and Patrick, 1986), which could augment cocaine-induced hypophagia and further exacerbate cocaine preferences.

MATERIALS AND METHODS

Sprague Dawley rats ($n = 50$ /sex; Charles Rivers, age 70–80 days upon arrival) were housed in same-sex pairs in standard laboratory cages and maintained on a 14L:10D light-cycle ('lights-off' at 0800 hours) with *ad lib* chow and water. Procedures were conducted between 0900 and 1600 hours and were in accordance with the NIH Guide for the Care and Use of Laboratory Animals and preapproved by the University of Michigan IACUC.

Animals were fitted with indwelling jugular catheters as previously described (Westenbroek *et al*, 2013), with some also undergoing stereotactic surgery for microdialysis guide cannula implantation (SciPro; MAB 6.14G) in the left NAc (AP: +1.7 mm and ML: +0.8 mm from Bregma, DV: –6.0 mm from skull)—an obturator extended an additional 2 mm. Rats were single housed post surgery and catheters were flushed daily with bacteriostatic saline containing gentamicin (3 mg/ml) and heparin (20 U/ml). Patency was verified weekly with 0.05–0.1 ml methohexital (7.5 mg/ml). Animals were weighed daily and the estrous cycle was monitored by daily vaginal lavage.

Self-Administration and Estrous Cycle Effects

Self-administration was conducted in standard operant chambers (Med Associates) using a fixed ratio (FR) schedule 4 days a week (FR1 during Week 1 and FR5 thereafter) and a progressive ratio (PR) schedule once a week (Supplementary Figure S1; Perry *et al*, 2013). On the FR schedule, the house light was illuminated during three 30-min active sessions

(pellet-only, cocaine-only, and choice), and was extinguished during two intervening 30-min 'off' sessions. Reward availability (pellet and/or cocaine) was indicated by illumination of the cue-light inside each nose port, which was inactivated for 40 s after reward delivery. Nose pokes in the active pellet hole resulted in the delivery of one food pellet (F0059, 45 mg, Banana Flavor, BioServ); nose pokes in the active cocaine hole resulted in an infusion (cocaine hydrochloride, 0.4 mg/kg per infusion). Reward delivery in choice sessions inactivated both holes for the 40-second timeout. The sequence of cocaine-only and pellet-only sessions was alternated daily. Cocaine preference was defined as the maintenance of infusion ratios twice as large as pellet ratios for 3 consecutive sessions. PP rats earning ≤ 2 infusions/day by the end of self-administration were labeled 'abstaining' (ABST).

Motivation, as defined by the final completed ratio or breaking point (BP), was examined simultaneously for both rewards using a concurrent PR schedule that independently increased through an exponential series for each reward: 1, 3, 6, 9, 12, 17, 24, 32, 42, 56, 73, 95, 124, 161, 208... (Richardson and Roberts, 1996). The concurrent PR schedule produces comparable results as 'single-reward' PR schedules (Perry *et al*, 2013). Ratio completion on each hole resulted in delivery of the associated reward and 5-s inactivation of that hole. Failure to complete the current ratio within 60 min resulted in inactivation of that hole for the remainder of the test, which lasted 6 h or until both holes were inactivated (whichever occurred first).

Numbers of infusions and pellets earned during cocaine-only and pellet-only sessions were aligned to the proestrous/estrous (PE) stage for each female for each week. P and E stages were combined because most females only displayed one or the other per cycle, which is typical for this phase of the light cycle (Becker, 2005). In the few estrous cycles with both, data were aligned to P and E was designated +1. Body weight change from the previous day was also aligned to estrous cycles. Mean were obtained for the last 5 weeks of self-administration (Weeks 1–2 omitted due to acquisition-related variable responding).

Microdialysis

Microdialysis probes (SciPro; MAB 6.14.2) were inserted and flushed with Ringer's (1.5 μ l/min, 60 min) in microdialysis chambers (Med Associates, PHM-125B) containing food and water. Afterwards, the inlet/outlet tubing was disconnected while probes remained in the guide protected by custom-built stainless-steel caps, and animals were returned to their home cages.

Inlet/outlet tubing was reconnected ~24 h later (half before, half after self-administration). Six 10-min baseline samples were collected at least 45 min post reconnection. Subjects received a non-contingent cocaine infusion (1.2 mg/kg, i.v.) and six additional 10-min samples (C1–C6) were collected. Microdialysis was conducted over 4 consecutive days during Weeks 2 and 7 to examine changes over time (Supplementary Figure S1B). Raw values for each day were converted to percent baseline (mean of three last baselines). Cocaine-induced DA overflow was consistent across days and unaffected by the estrous cycle (Supplementary Figure S3). Therefore, means of the multiple days were used for analyses.

Dialysate DA content was determined by HPLC with electrochemical detection (C-18 column, ESA Biosciences, HR-80X3.2, 3 μ m particle size, 80 mm length) with mobile phase (1.4 mM octanesulfonic acid and 20% methanol, pH 4.6–4.8) pumped at 0.7 ml/min at 27°C. Potentials (–75/+100 mV) were applied to a dual coulometric analytical cell (ESA model #5014B) connected to a Coulochem II/III detector, with the latter potential used to determine [DA] against a 1-pg standard. Probe placement was examined in horizontal sections. Only data from animals with track marks within the NAc were included (Supplementary Figure S4).

Pharmacological Manipulations

After 7 weeks, animals were treated in counter-balanced order with the non-selective β -AR antagonist ((S)-(–)-propranolol, 10 mg/kg, i.v., Tocris Bioscience), the α 1-AR antagonist (terazosin, 2 mg/kg, i.v., Tocris Bioscience), or vehicle (1 ml/kg saline, i.v.). Doses were chosen for being well-below lethal thresholds and biologically active (Alonso-Galicia *et al*, 1996; Kyncl, 1986). Treatments were administered 15 min before self-administration for 5 consecutive days (Supplementary Figure S1C). Subjects shifting preferences during treatment received vehicle the next week to determine whether it was permanent. In such cases, treatments were repeated and only data from the final period were used.

Statistics

Analyses were performed with SPSS (IBM, v21.0). Q–Q plots, Shapiro–Wilk, and Levene's tests were used to examine data for normality and homoscedasticity. Box–Cox power transformations identified optimal transformations (Supplementary Table S1). Thirty-one rats did not complete the 7 weeks of self-administration due to patency loss or complications related to the craniotomy surgery/microdialysis.

Cocaine and pellet BP were analyzed by repeated-measures ANOVA with between-subject (preference and sex) and within-subject (week) variables. General changes in behavior across three time blocks (Week 1, Weeks 2–6, and Week 7) were examined with pre-planned contrasts. Fisher's Exact tests were used to analyze whether the proportion of CP females was greater than males after Week 7 and during the final week of vehicle. Raw data aligned to the estrous cycle were analyzed with repeated measures ANOVA with between-subject (preference) and within-subject (stage) variables.

Microdialysis data were analyzed by repeated-measures ANOVA with between-subject (preference and sex) and within-subject (time, early vs late, and sample, C1–C6) variables. Pair-wise comparisons were only made between preferences within a time period, or between time periods for each preference using Fisher's LSD test.

Pharmacological manipulations were analyzed with repeated-measures ANOVA with between-subject (preference) and within-subject (treatment) variables. Pair-wise comparisons were only made against the vehicle treatment within each preference, and between all three preferences within each treatment using Fisher's LSD test. Choice session data were analyzed with Friedman's test followed by

Wilcoxon signed-rank tests to identify treatment effects within preferences, and with Kruskal–Wallis tests to identify preference effects within treatments. Preference shifts during treatments were examined with McNemar's test.

To simplify analyses, FR data were summed each week to collapse 4 consecutive days into single weekly measures. Repeated-measures ANOVA were conducted with sphericity assumed modeling, and Greenhouse–Geisser and Huynh–Feldt adjustments were applied as appropriate. Results were considered significant at $p < 0.05$ for all analyses.

RESULTS

Self-Administration, Sex Differences, and Estrous Cycle

Self-administration data on the FR schedule (Supplementary Figure S2) were consistent with our previous report (Perry *et al*, 2013). By Week 7, 42% of females (13/31) and 26% of males (10/38) had developed cocaine preferences. Additional 6 animals met CP criteria during the final vehicle week, resulting in 58% CP females (18/31) and 29% CP males (11/38). While the proportion of CP females was greater than males at both Week 7 and the final vehicle week, only the latter reached statistical significance ($p = 0.027$ by Fisher's Exact test).

Cocaine motivation (Figure 1a) was affected by preference ($F_{2,50} = 84.43$, $p < 0.001$), week ($F_{6,300} = 19.55$, $p < 0.001$), and week $\times$ preference interaction ($F_{12,300} = 5.15$, $p < 0.001$). ABST rats showed consistently low cocaine BP that did not change over time. In contrast, cocaine motivation increased in PP and CP rats, such that motivation in Weeks 2–6 was greater than Week 1 ($p < 0.001$ for both), and motivation in Week 7 was greater than Week 1 ($p < 0.001$ for both) and Weeks 2–6 ($p = 0.019$ and $p < 0.001$, respectively). CP rats always maintained higher cocaine BP than PP and ABST rats ($p < 0.001$ for all), whereas cocaine BP of PP rats were only greater than ABST rats during Weeks 2–6 and Week 7 ($p < 0.001$ for both).

Pellet motivation (Figure 1b) was affected by preference ($F_{2,50} = 3.82$, $p = 0.029$) and week ($F_{6,300} = 7.68$, $p < 0.001$). ABST and PP rats showed an asymptotic increase in pellet BP, such that Weeks 2–6 ($p \leq 0.003$ for each) and Week 7 ($p \leq 0.002$ for each) were greater than Week 1, but not different from each other. CP rats also showed increased pellet BP from Week 1 to Weeks 2–6 ($p < 0.001$); however, by Week 7 their motivation was lower than Weeks 2–6 ($p = 0.047$) and not different from Week 1. Pellet BP were similar among all preference groups during Week 1, whereas CP rats had lower pellet BP than PP rats during Weeks 2–6 ($p = 0.018$) and both ABST and PP rats during Week 7 ($p = 0.005$ and $p = 0.012$, respectively).

There were no effects of sex or interactions involving sex and any factor on FR or PR measures. When FR data were aligned to the estrous cycle (Figure 2), there was a robust stage effect on pellet intake ($F_{3,66} = 21.16$, $p < 0.001$), but not infusions. Females earned fewer pellets during PE compared with the other stages ($p < 0.001$ for each), which were not different. There were no effects of preference and no interactions between preference and stage on pellet intake, whereas preference affected infusions ($F_{2,22} = 27.19$, $p < 0.001$), with ABST, PP, and CP rats all displaying different levels of intake ($p < 0.003$ for each). The same

Figure 1 Changes in motivation for cocaine and food pellets over the course of self-administration. (a) Cocaine BP. (b) Pellet BP. Time blocks that do not share a letter are different from one another within a give preference group ($p < 0.05$). The far right section in each panel represents the same data from the 25 CP rats segregated by whether individuals were still 'pellet preferring' (open circles, 'before CP') or were displaying cocaine preferences (closed circles, 'after CP') at each time. The numbers associated with each point represent the number of CP individuals in each subgroup in each given week. Significant difference from PP (* $p < 0.05$) and ABST rats (# $p < 0.05$). Vertical lines represent SEM. ABST, abstaining; BP, breaking point; CP, cocaine preferring.

results were obtained with ranked data (Supplementary Figure S5).

The estrous cycle influenced weight gain ($F_{3,66} = 38.60$, $p < 0.001$), whereas there was no effect of preference or interaction between preference and stage (Figure 2b). Weight gain leveled off the day before PE, with females losing even more weight in PE, such that these stages were significantly different from all others ($p < 0.001$ for all).

Microdialysis

Analysis of cocaine-induced DA overflow in the NAc revealed main effects of time ($F_{1,19} = 5.40$, $p = 0.031$) and sample ($F_{5,95} = 194.62$, $p < 0.001$), time $\times$ sample interaction ($F_{5,95} = 4.91$, $p = 0.032$) and time $\times$ sample $\times$ preference interaction ($F_{10,95} = 4.05$, $p = 0.027$). The main effect of sex and all interactions involving sex were not significant.

Early during self-administration, there were no differences in cocaine-induced DA between preference groups (Figure 3). Late during self-administration, cocaine-induced DA was attenuated in CP rats compared with their earlier response (C1: $p < 0.001$, C2: $p = 0.001$, C3: $p = 0.042$) and the late responses of ABST (C1: $p = 0.007$, C2: $p = 0.021$) and PP rats (C2: $p = 0.002$, C3: $p = 0.002$, C4: $p = 0.011$). There were no differences between early and late DA responses in ABST or PP rats, and the late responses of ABST and PP rats were not different.

Pharmacological Manipulations

FR5 schedule. Cocaine-only session infusions (Figure 4a) were affected by preference ($F_{2,24} = 82.68$, $p < 0.001$), treatment ($F_{2,48} = 26.94$, $p < 0.001$), and preference $\times$ treatment interaction ($F_{4,48} = 4.59$, $p = 0.003$). Propranolol reduced cocaine intake in CP and PP rats ($p \leq 0.004$ for each).

Figure 2 The estrous cycle affected pellet intake and weight gain, but not cocaine intake. (a) The number of pellets earned in the pellet-only sessions was affected by the estrous cycle, whereas there was no effect of preference. In contrast, infusion number was affected by preference, but not the estrous cycle. The lack of a preference effect on pellet intake likely reflects averaging across multiple weeks, during which not all CP females were displaying cocaine preferences. The same effects were observed for intake during choice sessions (data not shown). (b) Weight gain was robustly affected by the estrous cycle in all preference groups, which confirms that females continued to cycle normally throughout self-administration. Therefore, the lack of estrous cycle effects on cocaine intake cannot be attributed to alterations in hormone fluctuations across the cycle (at least in regard to those affecting weight and food intake). Data were averaged across the last 5 weeks of self-administration and aligned to the proestrous/estrous (PE) stage of the cycle. The two days before PE (-2 and -1) correspond with diestrus I and diestrus II, whereas the day after PE (+1) corresponds with metestrus or sometimes estrus (see text for details). Stages without common letters are significantly different from one another. Intake in CP rats was significantly different from PP and ABST rats ($*p < 0.05$ for each). Intake in PP rats was significantly different from CP and ABST rats ($\#p < 0.05$ for each). Vertical lines represent SEM. ABST, abstaining; CP, cocaine preferring.

Figure 3 Changes in cocaine-induced DA overflow in the NAc over self-administration. (a) Rats received a single non-contingent cocaine infusion (1.2 mg/kg, i.v.) early (Week 2, solid lines) and again late during self-administration (Week 7, dashed lines). Cocaine-induced DA overflow was significantly attenuated in CP rats during Week 7 compared with their earlier response ($*p < 0.05$) and the late responses of ABST and PP rats ($\#p < 0.05$ compared with late CP). Data are repeated measures from 11 ABST rats (5 female, 6 male, white circles), 5 PP rats (2 female, 3 male, gray circles) and 9 CP rats (5 female, 4 male, black circles). Basal DA values in pg per 10 min sample were not different between groups at either time point: ABST rats (early: 7.2 ± 1.9 , late: 11.4 ± 2.7), PP rats (early: 6.3 ± 1.6 , late: 4.4 ± 1.3), and CP rats (early: 9.3 ± 1.2 , late: 11.9 ± 3.2). (b) Both CP males and females displayed attenuated cocaine-induced DA overflow during Week 7 compared with Week 2 ($*p < 0.05$). Vertical lines represent SEM. ABST, abstaining; CP, cocaine preferring; DA, dopamine; NAc, nucleus accumbens; PP, pellet preferring.

Compared with their intake during vehicle, propranolol reduced infusion number similarly in PP and CP rats ($32 \pm 9.8\%$ and $35 \pm 3.7\%$, respectively). PP and CP rats earned more infusions than ABST rats during all treatments ($p < 0.001$ for all), whereas CP rats only earned more infusions than PP rats during vehicle ($p = 0.015$) and terazosin ($p = 0.012$).

Choice session infusions (Figure 4b) were also affected by preference (VEH: $H(2) = 20.66$, $p < 0.001$; PRO: $H(2) = 20.69$, $p < 0.001$; TER: $H(2) = 19.76$, $p < 0.001$), with a treatment effect in CP rats ($k = 3$, $F = 13.13$, $p = 0.001$). Propranolol

reduced cocaine intake in CP rats ($p < 0.001$), reflecting a $24 \pm 4.4\%$ decrease from vehicle. CP rats earned more infusions than ABST and PP rats during all treatments ($p \leq 0.002$ for each), whereas ABST and PP rats were not different. There were no effects of terazosin on infusion number in any group.

Pellet-only session pellets (Figure 4c) were affected by preference ($F_{2,24} = 10.01$, $p = 0.001$), treatment ($F_{2,48} = 32.38$, $p < 0.001$), and preference $\times$ treatment interaction ($F_{4,48} = 7.25$, $p < 0.001$). Propranolol reduced pellet intake in PP and CP rats ($p = 0.004$ and $p < 0.001$, respectively), with

Figure 4 Effects of propranolol (PRO) and terazosin (TER) on cocaine and pellet intake. (a) Cocaine-only sessions: PRO reduced cocaine infusions in both PP and CP rats. (b) Choice session infusions: PRO reduced cocaine infusions in CP rats. The intake of the four CP rats most affected by TER ($n=4$, white circles in far right section of each panel) was substantially lower than their intake during VEH and PRO treatments, which is not apparent in the overall CP group mean and SEM. (c) Pellet-only sessions: PRO reduced pellet intake in PP and CP rats, whereas TER increased pellet intake in CP rats. (d) Choice session pellets: PRO reduced pellet intake in PP rats, whereas TER increased pellet intake in CP rats, which was largely due to the four CP individuals that reverted to pellet preferences during TER. For all panels, preference groups without common letters are significantly different from one another within a given treatment ($p < 0.05$). Treatment differs from vehicle (VEH) condition within a given preference group ($*p < 0.05$). Vertical lines represent SEM. Comparisons were not made between preference groups with different treatments. ABST, abstaining; CP, cocaine preferring; PP, pellet preferring.

significantly greater reduction in CP rats ($49 \pm 6.3\%$) compared with PP ($12 \pm 5.1\%$, $p = 0.012$) and ABST rats ($3 \pm 2.9\%$, $p < 0.001$) (preference effect: $H(2) = 16.33$, $p < 0.001$). Terazosin increased pellet intake in CP rats ($p = 0.011$). CP rats earned fewer pellets than ABST and PP during vehicle ($p \leq 0.023$ for each) and propranolol ($p < 0.001$ for each), and fewer than PP rats during terazosin ($p = 0.03$).

Choice session pellets (Figure 4d) were also affected by preference (VEH: $H(2) = 19.80$, $p < 0.001$; PRO: $H(2) = 20.01$, $p < 0.001$; TER: $H(2) = 15.11$, $p = 0.001$), with significant treatment effects in PP and CP rats ($k = 3$: $F = 6.87$, $p = 0.032$; $F = 19.60$, $p < 0.001$, respectively). Propranolol reduced pellet intake in PP rats ($p = 0.014$), reflecting a $15 \pm 6.5\%$ reduction. Terazosin increased pellet intake in CP rats ($p = 0.002$), which was largely due to preference shifts in $\sim 30\%$ of CP individuals. Shifts were apparent on the first day and lasted 1–4 days (4 days: two rats, 3 days: one rat, 1 day: one rat; Supplementary Figure S6). Two additional CP rats showed no preference (NP) for 1 day, such that terazosin significantly shifted preferences compared with vehicle (CP reverting to NP/PP, McNemar's test = 4.17, $p = 0.031$). All six shifting rats were female, whereas none of the five CP males shifted preferences. As a group, CP rats earned fewer pellets than ABST and PP rats in choice sessions during all treatments ($p \leq 0.002$ for each).

PR schedule. Cocaine BP (Figure 5a) were affected by preference ($F_{2,24} = 86.38$, $p < 0.001$) and preference $\times$ treatment interaction ($F_{4,48} = 7.95$, $p < 0.001$). Pellet BP

(Figure 5b) were also affected by preference ($F_{2,24} = 7.81$, $p = 0.002$) and treatment ($F_{2,48} = 8.87$, $p = 0.001$). Propranolol increased cocaine motivation in CP rats ($p = 0.004$) and reduced it in ABST rats ($p = 0.018$). Terazosin increased pellet motivation in all groups compared with vehicle ($p = 0.002$). Cocaine motivation was different between all three preferences under all treatments ($p \leq 0.003$ for each), whereas CP rats had reduced pellet motivation compared with ABST and PP rats during vehicle ($p = 0.048$ and $p = 0.027$, respectively) and propranolol ($p \leq 0.005$ for each).

DISCUSSION

Our results demonstrate that even though more female rats than males displayed a cocaine preference, both male and female CP rats exhibited attenuated cocaine-induced DA overflow in the NAc after the cocaine preference developed. Furthermore, we demonstrated differential effects of $\alpha 1$ - and β -AR antagonists on intake and motivation for drug and food rewards that suggest altered NE neurotransmission in CP rats.

Our finding that pellet intake and weight, but not cocaine intake, vary with the estrous cycle confirms our previous finding (Perry *et al*, 2013) and is consistent with results from another choice procedure (Kerstetter *et al*, 2012). Previous work has found that estradiol enhances acquisition of cocaine self-administration as well as cocaine intake and acute motivation (refer to Becker *et al* (2012) for review). This phenomena is similar to the effects of estradiol on

Figure 5 Effects of propranolol (PRO) and terazosin (TER) on motivation for cocaine and pellets. (a) PRO increased cocaine BP in CP rats and reduced them in ABST rats. (b) TER increases pellet BP in all groups; however, pair-wise comparisons were only significant in CP rats, which most likely reflects a power issue, as effect sizes were all relatively large (Cohen's $d = 1.84, 0.78$ and 0.83 for ABST, PP, and CP, respectively). The far right section of each panel shows the data for the CP rats that shifted to pellet preferences during TER treatment ($n = 4$, white circles), which shows that pellet BP were generally shifted upwards in all CP rats, not just the four most affected individuals. Preference groups without common letters are significantly different from one another within a given treatment ($p < 0.05$). Treatment differs from vehicle (VEH) condition within given preference group ($*p < 0.05$). Vertical lines represent SEM. Comparisons were not made between preference groups with different treatments. ABST, abstaining; CP, cocaine preferring; PP, pellet preferring.

maternal behavior, where estradiol priming enhances initial acquisition and performance, but the cues from the pups maintain the behavior once established (Numan, 2006).

The repeated PR data extended our previous findings in which motivation was only examined twice during self-administration (Perry *et al*, 2013). We now demonstrate that pellet motivation increases over time in all groups and is selectively attenuated in CP rats once cocaine preferences develop. In addition, the 'before' and 'after' data show that the patterns of CP group means (ie, 'escalating' cocaine BP, 'declining' pellet BP) primarily reflect the cumulative transition of CP rats to their final preference designation and not changes within individuals after shifting.

The attenuated cocaine-induced DA overflow in the NAc of CP rats is consistent with human imaging studies that also demonstrate reduced striatal DA neurotransmission in cocaine addicts (Martinez *et al*, 2009; Volkow *et al*, 1997). Individuals with the most attenuated amphetamine-induced DA were more likely to choose cocaine over alternative monetary rewards (Martinez *et al*, 2007), which is strikingly consistent with the neurochemistry and choice behavior of

CP rats. While others have reported reduced DA responses following cocaine self-administration (Ferris *et al*, 2011; Gerrits *et al*, 2002), the longitudinal nature of our experiment revealed that the attenuation occurred after cocaine preferences developed, which may contribute to the increased cocaine intake of CP rats (Guillem *et al*, 2013; Lau and Sun, 2002; Wise *et al*, 1995). Our data from PP rats suggest that cocaine exposure itself does not attenuate cocaine-induced DA in the NAc, which is consistent with other studies linking escalation (but not intake) to changes in DA neurotransmission (Willuhn *et al*, 2014). Sex differences and hormone effects on cocaine-induced DA in the NAc and striatum (the latter of which has received more attention) are more pronounced in gonadectomized animals (refer to Becker *et al* (2012) for review). The lack of sex differences on cocaine-induced DA in the NAc of our gonad-intact rats is consistent with another study (Holly *et al*, 2012). However, the use of additional cocaine doses might have revealed more subtle sex differences and/or estrous cycle effects.

Propranolol reduced infusions on the FR5 schedule and increased cocaine BP on the PR schedule—both consistent with enhanced cocaine-induced DA overflow in the NAc. Increased DA would lead to longer inter-infusion intervals and hence fewer infusions (FR5 schedule), whereas it would lead to longer occupation of the 'compulsion zone' and increased likelihood of completing the current ratio (PR schedule). (Goldberg and Gonzalez, 1976; Harris *et al*, 1996; Norman and Tsibulsky, 2006; Willuhn *et al*, 2014; Wise *et al*, 1995). Propranolol also reduced pellet intake on the FR5 schedule in PP and CP rats with negligible effects on motivation, which is consistent with another study ((Harris *et al*, 1996), but see the study by Goldberg and Gonzalez (1976)), suggesting greater satiety/anorexia—potentially via enhanced NE overflow and subsequent $\alpha 1$ -AR activation in (hypothalamic) feeding circuits (Levone *et al*, 2015; Tuross and Patrick, 1986; Wellman *et al*, 2002). In this regard, the greater propranolol-induced hypophagia in CP rats may reflect more pronounced alterations in NE neurotransmission. Therefore, future studies should examine changes in cocaine-induced NE and $\alpha 1$ - and β -AR and NE transporter (NET) expression. Increased NET expression may be particularly relevant to the CP phenotype, as NET is upregulated in monkeys self-administering cocaine (Beveridge *et al*, 2005) and human cocaine users (Mash *et al*, 2005).

Terazosin had no direct effects on cocaine self-administration. Others have shown that $\alpha 1$ -AR antagonists reduce cocaine-induced hyper-locomotion, hypophagia, and reinstatement in rats (Mitrano *et al*, 2012; Wellman *et al*, 2002; Zhang and Kosten, 2005) and subjective effects in humans (Newton *et al*, 2012), with marginal effects on intake (Wee *et al*, 2008; Woolverton, 1987). While terazosin has limited blood-brain barrier (BBB) penetration, high peripheral doses recapitulate effects of lower central doses (Stone *et al*, 1999), suggesting some may enter the brain. Alternatively, terazosin may affect pellet intake/motivation via peripheral actions or through brain regions outside the BBB (Fry *et al*, 2007). This may explain the lack of direct effects on cocaine measures, which presumably requires central $\alpha 1$ -AR blockade (Mitrano *et al*, 2012). Therefore, additional work is required to determine terazosin's site/mechanism of action, which largely blocked cocaine's acute anorectic effects in CP rats (Supplementary Figure S7),

increased motivation for the alternative food reward, and acutely reversed preferences in a small number of (female) CP rats. Thus, $\alpha 1$ -AR antagonists may shift the subjective balance between drug and non-drug rewards and serve as effective adjuncts for interventions targeting cocaine's reinforcing effects (Newton *et al*, 2012).

Despite the fact that women cocaine users are equally likely to become dependent as men (Cotto *et al*, 2010) and addiction is associated with higher rates of psychopathologies in women (Chen *et al*, 2011), the bulk of knowledge regarding drug abuse is based on studies in males. Our results are consistent with greater vulnerability in females, as they were more likely to develop cocaine preferences. However, our use of preferences and motivation to identify an addiction severity spectrum (Supplementary Figure S8; Supplementary Table S2) suggests more equivalent rates between the sexes. Nevertheless, similar behavior does not necessarily mean that the underlying neurobiology is identical in males and females. Here we see similar patterns of changes in NAc DA in CP males and females, but potentially different responses to the $\alpha 1$ -AR antagonist.

In conclusion, our results indicate roles for both DA and NE in the pathology of addiction. Furthermore, more complex behavioral paradigms are required to capture aspects of addiction beyond reinforcement—particularly those impacting mental and physical health, and quality of life, which are often worse in addicts and can interfere with treatment retention and long-term abstinence (Chen *et al*, 2011; Degenhardt and Hall, 2012; Ersche *et al*, 2013; Morales-Manrique *et al*, 2011). Our results with the $\alpha 1$ -AR antagonist directly address the nutritional/metabolic consequences of addiction (Ersche *et al*, 2013), and provide a framework for examining how derogation of other natural rewards influences addiction and recovery.

FUNDING AND DISCLOSURE

Research was supported by funding from NIDA (DA012677 to JBB, DA032856 to JBB and ANP, and support to ANP from T32 DA007268). Cocaine hydrochloride was provided by the NIDA Drug Supply Program (the Chemistry & Physiological Systems Research Branch, Division of Basic Neuroscience & Behavioral Research, the National Institute on Drug Abuse, NIH). The authors declare no conflict of interest.
