Nicotine Increases Codeine Analgesia Through the Induction of Brain CYP2D and Central Activation of Codeine to Morphine

CYP2D metabolically activates codeine to morphine, which is required for codeine analgesia. Permeability across the blood–brain barrier, and active efflux, suggests that initial morphine in the brain after codeine is due to brain CYP2D metabolism. Human CYP2D is higher in the brains, but not in the livers, of smokers and 7-day nicotine treatment induces rat brain, but not hepatic, CYP2D. The role of nicotine-induced rat brain CYP2D in the central metabolic activation of peripherally administered codeine and resulting analgesia was investigated. Rats received 7-day nicotine (1 mg/kg subcutaneously) and/or a single propranolol (CYP2D mechanism-based inhibitor; 20 µg intracerebroventricularly) pretreatment, and then were tested for analgesia and drug levels following codeine (20 mg/kg intraperitoneally) or morphine (3.5 mg/kg intraperitoneally), matched for peak analgesia. Nicotine increased codeine analgesia (1.59X AUC_{0–30 min} vs vehicle; $p < 0.001$), while propranolol decreased analgesia (0.56X; $p < 0.05$); co-pretreatment was similar to vehicle controls (1.23X; $p > 0.1$). Nicotine increased, while propranolol decreased, brain, but not plasma, morphine levels, and analgesia correlated with brain ($p < 0.02$), but not plasma ($p > 0.4$), morphine levels after codeine. Pretreatments did not alter baseline or morphine analgesia. Here we show that brain CYP2D alters drug response despite the presence of substantial first-pass metabolism of codeine and further that nicotine induction of brain CYP2D increases codeine response *in vivo*. Thus variation in brain CYP2D activity, due to genetics or environment, may contribute to individual differences in response to centrally acting substrates. Exposure to nicotine may increase central drug metabolism, not detected peripherally, contributing to altered drug efficacy, onset time, and/or abuse liability.

Neuropsychopharmacology (2015) **40**, 1804–1812; doi:10.1038/npp.2015.32; published online 18 February 2015

INTRODUCTION

The majority of cytochrome P450 (CYP)-mediated drug metabolism occurs in the liver; however, resulting plasma drug and/or metabolite levels do not always correlate with therapeutic effect (Ding and Kaminsky, 2003). Extra-hepatic CYP activity, specifically in the brain, may influence target-tissue drug concentration and effect (Krishna and Klotz, 1994; Michels and Marzuk, 1993). Experimentally, this has been explored, for example, by inhibiting rat brain CYP2B, which decreased the inactivation of the sedative-hypnotic propofol, resulting in a prolonged propofol effect and decreased the activation of the organophosphate chlorpyrifos reducing neurotoxicity (Khokhar and Tyndale, 2011, 2012).

CYP2D6 (herein referred to as CYP2D for all species) metabolizes a large proportion of drugs acting in the central nervous system (CNS) (eg, amphetamine, haloperidol, and

antidepressants), as well as endogenous neurochemicals (Zanger *et al*, 2004). The human CYP2D gene is genetically polymorphic, resulting in a wide range of metabolism phenotypes (Gaedigk *et al*, 2008), while brain CYP2D levels are altered by common compounds and increase with age (Mann *et al*, 2012; Miksys and Tyndale, 2004; Warner and Gustafsson, 1994; Yue *et al*, 2008). Rat and monkey brain, but not liver, CYP2D is induced by nicotine pretreatment, consistent with higher levels of human brain, but not liver, CYP2D in smokers (Miksys and Tyndale, 2004; Miller *et al*, 2014; Yue *et al*, 2008). Thus the combination of genetics, environmental inducers, and age contribute to a wide range of brain CYP2D activity, which may alter the metabolism and efficacy of CNS-acting substrate drugs.

CYP2D metabolizes codeine to its primary analgesic metabolite morphine, a step required for codeine analgesia (Adler *et al*, 1955; Chen *et al*, 1991; Pert and Snyder, 1973; Sindrup *et al*, 1992; Sindrup *et al*, 1990). This occurs in the liver, after which morphine crosses the blood–brain barrier (BBB) to interact with opioid receptors in the CNS and elicit analgesia. However, morphine is less permeable across the BBB than codeine and is actively effluxed (Bouw *et al*, 2000; Oldendorf *et al*, 1972). Coupled with this, brain concentrations of morphine after codeine administration do not

Received 17 October 2014; revised 21 January 2015; accepted 26 January 2015; accepted article preview online 29 January 2015

appear to be solely attributable to transfer of morphine across the BBB (Chen *et al*, 1990; Zhou *et al*, 2013). Thus, following codeine administration, the initial morphine present in the brain, and initial analgesia, may be due to brain CYP2D-mediated metabolism, rather than hepatic metabolism.

Our objectives were to model the role of human brain CYP2D in response to centrally acting drugs, through investigating rat brain CYP2D metabolic activation of codeine to morphine, in the presence of hepatic first-pass metabolism, in a rat model of codeine analgesia. Rat brain CYP2D has the ability to metabolize human CYP2D probe drugs and can be inhibited and induced *in vivo*, independently of hepatic CYP2D, allowing the modelling of a wide range of CYP2D activity within the brain, as postulated to exist in a heterogeneous population (Hiroi *et al*, 2002; Zhou *et al*, 2013). Whether the nicotine induction of brain CYP2D is sufficient to alter drug response *in vivo*, using a peripheral route of drug administration with substantial first-pass metabolism by the liver, is unknown. This study aims to demonstrate that variable brain CYP2D alters substrate drug metabolism and efficacy and provides further understanding to the functional role of CYP enzymes in the brain.

MATERIALS AND METHODS

Animals

Adult male Wistar rats (250–500 g; Charles River, St-Constant, QC, Canada) were housed in pairs or triplets with *ad libitum* access to food and water. Rats were maintained under a 12-h artificial light/dark cycle with experimentation occurring during the light cycle. Stress was reduced through acclimation to experimenters and apparatuses. All procedures were approved by the Animal Care Committee at the University of Toronto.

Drug Treatment

Codeine phosphate and morphine sulfate (PCCA, London, Canada) were dissolved in saline (0.9% NaCl; pH 7) and distilled water, respectively, and injected intraperitoneally (i.p.). The doses of codeine (20 mg/kg) and morphine (3.5 mg/kg) were chosen to match peak analgesia after testing multiple doses of codeine (20, 25 and 30 mg/kg) and morphine (0.5, 1, 2, and 3.5 mg/kg). Propranolol hydrochloride (Sigma-Aldrich, Oakville, Canada) was dissolved in artificial cerebrospinal fluid to deliver 20 µg base in 4 µl via intracerebroventricular (i.c.v.) injection 24 h prior to codeine or morphine administration. Propranolol is a CYP2D mechanism-based inhibitor, metabolized by CYP2D; the metabolite covalently binds and inactivates CYP2D (Narimatsu *et al*, 2001). Propafenone hydrochloride (Sigma-Aldrich), a CYP2D competitive inhibitor (Xu *et al*, 1995), was dissolved in a 20% (w/v) solution of 2-hydroxypropyl-β-cyclodextrin (Sigma-Aldrich) in water to deliver 40 µg base in 4 µl i.c.v., 5 min prior to codeine or morphine administration. Two mechanistically and structurally distinct CYP2D inhibitors were used to reduce the possibility of off-target effects other than inhibition of codeine metabolism. Nicotine bitartrate (Sigma-Aldrich) was dissolved in saline and given subcutaneously (s.c.) at 1 mg base/kg daily for 7 days, which results

in elevated rat brain, but not liver, CYP2D levels as previously described (Yue *et al*, 2008).

Cannulation Surgeries for Multiple i.c.v. Injections

Rats utilized for brain CYP2D-inhibition experiments were surgically implanted with i.c.v. cannulas into their right lateral ventricle (Zhou *et al*, 2013). Screw anchors (BASi, West Lafayette, USA) were implanted into the skull to serve as an anchor to the DuraLay inlay pattern resin (Reliance Dental Mfg. Co., Worth, USA) used as an adhesive for the implanted cannula.

Nociceptive Testing of Codeine and Morphine Analgesia

Analgesia was measured by the tail-flick reflex test through the use of a tail-flick meter (Columbus Instruments, Columbus, OH, USA) (D'Amour and Smith, 1941). A thermal stimulus is applied to the rat's tail, ~5 cm from the distal end, and the time of onset of stimulus to a vigorous tail flick is recorded as the tail-flick latency (TFL). Prolongation of the TFL is an indication of both spinally and supra-spinally mediated analgesia (Le Bars *et al*, 2001). The thermal strength of the tail-flick meter was adjusted to obtain baseline TFLs around 3 s; a cutoff of 10 s was used to avoid damage. TFLs were measured twice in each rat 24 h prior to experimentation, and the mean was used as the individual rat's baseline TFL. Analgesia was expressed as a percentage of the maximal possible effect (%MPE) (Dewey and Harris, 1971).

$$\%MPE = \frac{(\text{postinjection latency} - \text{baseline latency})}{(\text{maximum cutoff} - \text{baseline latency})} \times 100\%$$

Analgesia Experimental Design

For pretreatment experiments, codeine or morphine was given 24 h after i.c.v. pretreatment injection (propranolol or vehicle) and/or 8 h after the last s.c. pretreatment injection (nicotine or saline). After opioid administration, analgesia was assessed by TFL every 5 min for 30 min and then every 10 min for the next 30 min. Within-animal designs were used where possible in which, after a 1-week washout period, rats were crossed over to a comparator pretreatment group and retested or killed for pharmacokinetic analysis.

Plasma and Brain Sample Preparation

For analysis of codeine and morphine from the plasma and brain, rats were pretreated, then administered codeine, tested for TFL at 15 min postinjection, and killed by decapitation. Trunk blood was centrifuged at 5000 g for 10 min. Half-brains were homogenized in 1:3 (w/v) 0.01 N HCl and centrifuged at 5000 g for 10 min. Nicotine plasma samples were obtained on the seventh day of nicotine pretreatment via saphenous-vein blood draws.

HPLC Measurement of Plasma and Brain Drug/Metabolite Levels

Plasma and brain homogenate samples were analyzed as previously described (Zhou *et al*, 2013). In brief, 100 µl of

solid phase extract was analyzed by HPLC with ultraviolet detection at 214 nm (Agilent 1200 Separation Module, Palo Alto, CA, USA). Morphine, codeine, and internal standard (1 μ g 2-benzoxazolinone) were separated on an Agilent ZORBAX SB-C18 Column (250 mm $\times$ 4.6 mm I.D.; particle size, 5 μ m), with the retention times of 4.1, 9.0 and 16.7 min, respectively. The mobile phase used was methanol: phosphate buffer (29.3:70.7 (v/v); pH 5.8) with a flow rate of 1 ml/min. The limits of quantification were 5 and 10 ng/ml (5 and 50 ng/g for brain tissue) for morphine and codeine, with an extraction efficiency of 76.9 and 90.1%, respectively. Nicotine and cotinine were quantified by HPLC (Siu *et al.*, 2006).

Statistical Analyses

Data were analyzed through one-way or two-way repeated-measures ANOVA with Bonferroni corrections or unpaired (between animal) and paired (within animal) one-tailed *t*-tests, as indicated.

RESULTS

Analgesic Profiles and Morphine Concentrations Suggest Involvement of Brain CYP2D in Codeine Metabolism and Initial Codeine Analgesia

Codeine (20 mg/kg) resulted in a peak of analgesia around 15 min ($n=22$; Figure 1a) with morphine metabolite levels detectable in both plasma and brain ($n=5$; Figure 1b and c). This codeine dose used throughout provided analgesia below maximal %MPE, allowing for measurement of both increases and decreases in analgesia. Morphine (3.5 mg/kg) matched the peak analgesia level obtained from codeine, however, later at 30 min ($n=8$; Figure 1a). At 15 min, the morphine dose produced similar plasma morphine levels to those from codeine ($p>0.3$; $n=10$; Figure 1b), but lower brain morphine levels ($p<0.02$; Figure 1c), consistent with lower analgesia at this time point. This suggests that the early analgesia peak at 15 min following codeine, along with the high levels of brain morphine present, was due to morphine formed by central (brain) metabolism. The delayed peak in analgesia after morphine suggests that peripheral morphine, as compared with the more lipophilic codeine, crosses the BBB more slowly, therefore eliciting analgesia at a later time.

Pretreatment with Two Distinct CYP2D Inhibitors (i.c.v.) Decreased the First 30 min of Codeine-Induced Analgesia but Did Not Affect Morphine-Induced Analgesia

With a focus on the time frame (0–30 min postinjection) hypothesized to be associated with brain metabolism of codeine to morphine and the resulting peak in codeine-induced analgesia, the effect of inhibiting brain CYP2D was assessed using two structurally and mechanistically distinct CYP2D inhibitors. Compared with vehicle pretreatment, 20 μ g propranolol (mechanism-based inhibitor) pretreatment resulted in significantly lower %MPE at numerous time points ($n=16$ /group; Figure 2a) after codeine (20 mg/kg) administration, producing a significant reduction of the analgesic AUC_{0–30 min} ($p<0.01$; Figure 2b). Likewise, 40 μ g

Figure 1 The analgesic time course following codeine and morphine suggests peripheral morphine levels do not predict central morphine levels or analgesia. Codeine (20 mg/kg) produced an analgesic peak around 15 min postinjection ($T_{MAX} = 13 \pm 1.8$ min, mean $\pm$ SEM; $n=22$; a). A morphine dose (3.5 mg/kg), chosen to match peak analgesia from codeine, resulted in an equivalent albeit later analgesia peak around 30 min postinjection ($T_{MAX} = 27 \pm 4.9$ min; $n=8$). At 15 min postinjection, the time of the codeine analgesia peak, the morphine dose ($n=10$) produced similar plasma morphine levels to the codeine dose ($n=5$; b), and lower brain morphine levels (c) consistent with the lower analgesia. A between-animal study design was used; * $p<0.05$ compared with codeine (20 mg/kg) using an unpaired *t*-test.

propafenone (competitive inhibitor) pretreatment resulted in significantly lower %MPE ($n=6$ /group; Figure 2d), and analgesic AUC_{0–30 min} after codeine administration ($p<0.05$; Figure 2e).

As morphine is the active analgesic metabolite of codeine and not further metabolized by CYP2D, its analgesia should not be altered by changes in CYP2D activity. Compared with vehicle pretreatment, neither propranolol nor propafenone pretreatment altered %MPE ($p>0.1$ at all time points) or analgesic AUC ($p>0.1$) across any time frame after morphine administration ($n=5$ /group; illustrated for AUC_{0–30 min} and AUC_{30–60 min} in Figure 2c and f).

Pretreatment with CYP2D inhibitors also had no effect on baseline nociception; there was no difference between TFL prior to (3.52 ± 0.21 , mean $\pm$ SEM) and 24 h after vehicle (3.64 ± 0.16 s) or (3.72 ± 0.20 s) propranolol pretreatment ($n=16$; $p>0.2$), or TFL prior to (3.03 ± 0.14 s) and 5 min after vehicle (3.13 ± 0.14 s) or (3.18 ± 0.16 s) propafenone pretreatment ($n=6$; $p>0.2$). Together, this indicated that CYP2D inhibitor pretreatments had no effect on analgesia that was unrelated to their effects on codeine metabolism.

Figure 2 Inhibiting brain CYP2D reduced the first 30 min of codeine-induced analgesia but had no effect on morphine-induced analgesia. Compared with vehicle pretreatment, propranolol pretreatment (darker bar) resulted in significantly lower analgesia (%MPE; a) and area under the analgesia-time curve (AUC; b) for 0–30 min after codeine administration ($n = 16/\text{group}$). Propranolol pretreatment (darker bars) did not result in a difference in analgesic AUC_{0–30 min} or AUC_{30–60 min} (c) after morphine administration ($n = 5/\text{group}$; hatched bars). Compared with vehicle pretreatment, propafenone pretreatment (darker bar) resulted in significantly lower %MPE (d) and analgesic AUC_{0–30 min} (e) after codeine administration ($n = 6/\text{group}$). Propafenone pretreatment (darker bars) did not result in a difference in analgesic AUC_{0–30 min} or AUC_{30–60 min} (f) after morphine administration ($n = 5/\text{group}$; hatched bars). Error bars indicate SEM. A within-animal study design was used; for analgesia-time curves, * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$ using repeated-measures ANOVA with Bonferroni post hoc. For AUCs, * $p < 0.05$, ** $p < 0.01$ using paired t -tests.

7-Day Pretreatment with Nicotine, to Induce Brain CYP2D, Increased the First 30 min of Codeine-Induced Analgesia but Did Not Affect Morphine-Induced Analgesia

Nicotine administration induces rat brain CYP2D without altering hepatic CYP2D; rats were administered nicotine (1 mg/kg; s.c.) or vehicle (saline, 1 ml/kg; s.c.) and tested at 8 h after the seventh and final injection (Figure 3a), when brain CYP2D is significantly induced (Yue *et al*, 2008). On the final day of nicotine pretreatment, plasma nicotine levels peaked within the first 30 min and were undetectable at 8 h postinjection, the time of codeine or morphine administration and analgesia testing ($n = 16$; Figure 3b). Compared with vehicle pretreatment, 7 days of nicotine pretreatment resulted in significantly higher %MPE ($n = 20/\text{group}$; Figure 3a) after codeine administration, producing a significantly higher AUC_{0–30 min} ($p < 0.03$; Figure 3b).

The effect of nicotine pretreatment on morphine analgesia (3.5 mg/kg) was also tested; if nicotine's actions on increasing codeine-induced analgesia were via induced brain

CYP2D, no change in morphine-induced analgesia would be expected. Compared with vehicle pretreatment, nicotine pretreatment did not result in significantly altered %MPE ($p > 0.3$ at all time points) or analgesic AUC ($p > 0.3$) across any time frame after morphine administration ($n = 16/\text{group}$; illustrated for AUC_{0–30 min} and AUC_{30–60 min} in Figure 3e).

The effect of 7-day nicotine pretreatment on codeine and morphine analgesia from the tail-flick assay was also tested using the hot-plate assay (Eddy and Leimbach, 1952; Rowland *et al*, 1994). Compared with vehicle, nicotine pretreatment resulted in significantly higher %MPE (Supplementary Figure S1a) and a 2.46-fold greater AUC_{0–30 min} ($p < 0.01$; $n = 8/\text{group}$; Supplementary Figure S1b) after codeine administration, with no change in %MPE ($p > 0.2$ at all time points) or AUC ($p > 0.3$) across any time frame after morphine administration ($n = 5/\text{group}$; Supplementary Figure S1c in the Supplementary Materials S1).

TFLs were assessed prior to daily nicotine injections and at 8 h postinjection (the time at which codeine and morphine were tested). There was no change in preinjection TFL (Day

Figure 3 Nicotine-mediated induction of brain CYP2D increased codeine analgesia and had no effect on morphine-induced analgesia. Rats were administered nicotine (1 mg/kg; s.c.) or saline vehicle (s.c.) once daily for 7 days as outlined (a). As measured on the final day of nicotine pretreatment, plasma nicotine levels peaked within the first 30 min and were undetectable by 8 h, the time of codeine or morphine administration ($n = 16$; b). Mean plasma nicotine levels averaged over 8 h was approximately 70 ng/ml and over 24 h was approximately 25 ng/ml. Compared with vehicle pretreatment, nicotine pretreatment (darker bar) resulted in significantly higher %MPE (c) and analgesic $AUC_{0-30 \text{ min}}$ (d) after codeine administration ($n = 20$ /group). Seven days of nicotine pretreatment (darker bars) did not result in a difference in analgesic $AUC_{0-30 \text{ min}}$ or $AUC_{30-60 \text{ min}}$ (e) after a morphine injection ($n = 16$ /group; hatched bars). Error bars indicate SEM. A within-animal study design was used; for analgesia-time curves, $**p < 0.01$ using repeated-measures ANOVA with Bonferroni post hoc. For AUCs, $*p < 0.05$ using paired t -tests.

1: 5.4 ± 0.5 s, mean + SEM; Day 7: 5.3 ± 0.4 s; $p = 0.39$) or 8 h postinjection TFL (Day 1: 5.1 ± 0.5 s; Day 7: 4.7 ± 0.3 s; $p = 0.20$) and no change in TFL between preinjection and 8 h postinjection ($p > 0.1$) across each of the 7 days of nicotine injections. Together, with the lack of effect on morphine analgesia, this suggests that nicotine (as tested here) did not alter nociception during codeine and morphine testing, suggesting, instead, a direct effect on codeine analgesia via induction of brain CYP2D.

Pretreatment with a Mechanism-Based Brain CYP2D Inhibitor Blocked the Effect of Nicotine Induction of Brain CYP2D on Codeine Analgesia

Compared with vehicle pretreatment, when animals were pretreated with 7 days of nicotine, there was a significant increase in %MPE ($n = 12$ /group; Figure 4a) and resulting increase in analgesic $AUC_{0-30 \text{ min}}$ after codeine ($p < 0.001$; Figure 4b). Conversely, when animals were pretreated with propranolol, there was a significant decrease in %MPE and analgesic $AUC_{0-30 \text{ min}}$ after codeine administration ($p < 0.05$).

Co-pretreatment of propranolol blocked the nicotine-induced increase in codeine analgesia, likely through inhibiting the induced levels of brain CYP2D, and resulted in similar codeine to the vehicle pretreatment ($p = 0.8$). There was no significant difference in baseline TFL between the four pretreatment groups ($p > 0.3$). Thus the effect of propranolol and nicotine pretreatment together resulted in no net change in codeine-induced analgesia, suggesting that they were acting in opposing directions via the same mechanism, presumably through modification of brain CYP2D activity.

Variation in Brain CYP2D Altered Brain Metabolism of Codeine Without Affecting Hepatic CYP2D

To investigate whether the alterations in codeine analgesia correlated with changes in codeine metabolism *in vivo*, brain and plasma codeine and morphine levels were assessed after administration of the combination of pretreatments used previously (Figure 4). There was a significant correlation between plasma and brain codeine levels ($r = 0.60$; $p < 0.001$; Figure 5a) but not between morphine levels ($r = 0.14$;

Figure 4 Nicotine induction of brain CYP2D increased the first 30 min of codeine-induced analgesia, an effect that was blocked by inhibiting brain CYP2D. Compared with vehicle pretreatment, 7 days of nicotine pretreatment or propranolol pretreatment alone resulted in significantly higher and lower, respectively, %MPE (a) and analgesic AUC_{0–30 min} (b) after codeine administration. Compared with vehicle pretreatment, co-pretreatment of nicotine and propranolol together resulted in a significantly different %MPE and AUC_{0–30 min} than nicotine or propranolol pretreatment alone and no change in %MPE or AUC_{0–30 min} from vehicle pretreatment ($n = 12/\text{group}$). Error bars indicate SEM. A within-animal study design was used; * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, compared with vehicle, and # $p < 0.05$, ## $p < 0.01$, compared with the combination pretreatment, using repeated-measures ANOVA with a Bonferroni *post hoc* test.

$p = 0.26$; Figure 5b) at 15 min after codeine administration ($n = 26$). This suggests that at 15 min after codeine administration plasma morphine levels did not predict brain morphine levels, indicating the presence of barriers to morphine permeability across the BBB. In the same analysis, analgesia at 15 min correlated with brain morphine levels ($r = 0.41$; $p < 0.02$; Figure 5c) but not with plasma morphine ($r = 0.01$; $p = 0.48$; Figure 5d) at 15 min after codeine administration ($n = 26$), consistent with brain CYP2D-mediated codeine metabolism and resulting brain morphine levels, being responsible for codeine analgesia over the first 30 min after codeine administration.

Compared with vehicle pretreated rats ($48.5 \pm 2.0 \text{ ng/g}$, mean $\pm$ SEM), nicotine pretreated rats had significantly higher morphine levels in the brain ($54.7 \pm 2.4 \text{ ng/g}$; $p < 0.02$), propranolol pretreated trended towards lower morphine levels in the brain ($44.5 \pm 2.6 \text{ ng/g}$; $p = 0.2$), and rats co-pretreated with nicotine and propranolol had no difference in the brain morphine levels ($51.6 \pm 2.2 \text{ ng/g}$; $p = 0.8$) after codeine administration, all consistent with brain CYP2D-specific changes ($n = 8/\text{group}$). The three active pretreatment paradigms did not alter plasma morphine levels ($p > 0.7$, for all comparisons), suggesting that these pretreatments modified brain metabolism of codeine, without affecting hepatic metabolism.

DISCUSSION

This is the first study to demonstrate that brain CYP2D has a role in drug response even in the presence of substantial first-pass metabolism of codeine and further that nicotine induction of brain CYP2D can increase central drug metabolism and response *in vivo*. Previously, it was unknown whether the nicotine-induced levels of brain CYP2D were sufficient and possessed adequate cofactors *in situ* to alter CNS-acting drug metabolism and resulting drug effect *in vivo*. This is also the first study to show that

Figure 5 Codeine, but not morphine, levels correlate between plasma and brain; brain morphine levels reflect codeine analgesia. Plasma and brain codeine levels correlated significantly (a) at 15 min, suggesting that codeine equilibrated quickly between the plasma and brain compartments. There was no correlation between plasma and brain morphine levels following codeine administration (b). Analgesia correlated with brain morphine levels (c) but not with plasma morphine (d) at 15 min after codeine administration ($n = 26$). Pearson correlations were used.

this nicotine induction of brain CYP2D alters drug response and can be blocked with brain CYP2D inhibitors, suggesting the importance of the interplay of compounds that alter brain activity on centrally acting drug effect, including for orally administered drugs.

Codeine and morphine, given at doses resulting in equivalent plasma morphine levels at 15 min postinjection and peak analgesia, resulted in significantly different brain morphine levels and analgesia time lines, suggesting that hepatic metabolism of codeine to morphine was not solely responsible for the levels of brain morphine and centrally mediated analgesia after a codeine injection. Our findings suggest a significant role for variable brain metabolism in codeine analgesia; inhibiting brain CYP2D with two mechanistically distinct inhibitors decreased, while inducing brain CYP2D with nicotine increased, codeine analgesia and resulting brain morphine levels, effects that were selectively blocked by co-pretreatment. Furthermore, neither inhibiting nor inducing brain CYP2D altered baseline response, morphine, analgesia, or peripheral metabolism of codeine, suggesting that the pretreatments used to modify brain CYP2D did not have off-target effects on codeine's downstream mechanism of action.

The 7-day nicotine pretreatment paradigm resulted in average daily nicotine plasma levels of 25 ng/ml (Figure 3b), similar to those seen in human smokers (20–50 ng/ml) (Benowitz, 1999); similar to nicotine-treated animals, smoking is associated with higher human brain CYP2D (Mann *et al*, 2008; Miksys and Tyndale, 2004; Miller *et al*, 2014; Yue *et al*, 2008). Peripheral pharmacokinetics of codeine are similar in smokers and nonsmokers, consistent with our current animal studies, and with a lack of effect of smoking or nicotine treatment on hepatic CYP2D (Miller, 1990). Approximately 20% of the US population continues to smoke cigarettes; smokers have a greater risk of multi-drug use and dependency (Berg *et al*, 2013). Furthermore, the use of electronic cigarettes that deliver nicotine mimicking conventional cigarettes is increasing, particularly in adolescents (Dutra and Glantz, 2014). Opioid analgesics such as codeine, while widely accepted for the treatment of acute to chronic pain, are abused for their euphoric mood-altering properties, with the incidence of non-medicinal prescription opioid use increasing (Fischer *et al*, 2006). The reinforcing qualities of codeine come from its morphine metabolite, therefore for individuals with higher levels of brain CYP2D (eg, smokers) a more rapid exposure of the brain to morphine, through faster centrally mediated metabolic activation, could speed the onset time of codeine's reinforcing effects and increase its abuse liability (Kathiramalainathan *et al*, 2000; Tyndale *et al*, 1997). Increased central opiate activation may be one mechanism increasing the risk of smoking and opioid co-dependency (Richter and Ahluwalia, 2000). In support of this, the prevalence of repeated prescription frequency, and general non-medicinal prescription opioid use, is higher in both men and women with smoking dependence (Skurtveit *et al*, 2010). Although alternative mechanistic explanations exist, such as receptor cross-sensitization in the enhanced rewarding and psychomotor effects of morphine in rodents following nicotine treatment, nicotine's ability to alter drug metabolism within the brain may also contribute (Vihavainen *et al*, 2008).

In animals pretreated with chronic nicotine, there was a trend for a faster onset of analgesia; the T_{MAX} with brain CYP2D induction (14.6 ± 1.7 min, mean ± SEM) was shorter compared with vehicle pretreatment (18.8 ± 1.4 min; $p > 0.1$), brain CYP2D inhibition (17.1 ± 1.8 min; $p > 0.4$) and co-pretreatment (17.1 ± 1.8 min; $n = 12$ /group; $p > 0.5$ using a

two-way ANOVA against brain CYP2D induction). A shift in codeine analgesic T_{MAX} , due to enhancement of brain CYP2D metabolism, could contribute to a faster onset of codeine's clinical actions but may also increase its abuse liability. Individuals exposed to compounds that affect brain CYP2D levels and/or activity could present with varied profiles of both clinical effect and abuse potential to drugs that are activated (ie, codeine), or inactivated (ie, amphetamine) by CYP2D (Wu *et al*, 1997).

The absolute magnitude of the change in morphine levels, analgesia and T_{MAX} was likely blunted, due to the brain CYP2D inhibition paradigm employed, resulting from incomplete inhibition of CYP2D. A larger dose of propranolol (40 µg base in 4 µl), which reduced analgesia further, inhibited hepatic CYP2D (determined by *ex vivo* metabolic assays) suggesting that propranolol had crossed the BBB into the periphery and obscured the ability to focus solely on brain metabolism (Zhou *et al*, 2013). An active search is underway for alternative molecular-inhibition options for future experiments. In addition, brain CYPs are highly localized and respond to inducers and inhibitors with complex patterns of regulation that are both tissue and cell-type specific (Yue *et al*, 2008). For this reason, the direct correlation between brain regions associated with antinociception and with CYP2D protein affected by induction and inhibition is unclear. Thus global brain inhibition and homogenates were used as a way of capturing a more general picture, however, likely resulted in a muting of the propranolol effect. Further studies into brain regions corresponding to high opioid receptor and CYP2D protein density are warranted to elucidate the importance of region-specific brain CYP2D alterations on codeine metabolism and analgesia.

Nicotine has an important role in modulating pain transmission. Activation of the $\alpha 4\beta 2$ and $\alpha 7$ nicotinic acetylcholine receptor subtypes elicits analgesia and is purported to involve opioidergic neurons and endogenous opioid peptides; nicotine analgesia is decreased in μ -opioid receptor knockout mice (Berrendero *et al*, 2002; Carstens *et al*, 2001; Damaj *et al*, 2000; Dhatt *et al*, 1995). Furthermore, nicotine dependence and withdrawal can affect both opioid- and noxious stimulus-induced analgesia involving these receptors in the nucleus accumbens (Schmidt *et al*, 2001). For these reasons, it was important to control for nicotine's own potential effects on nociception and opioid action. There were no detectable levels of nicotine at 8 h postinjection, the time of codeine/morphine administration (Figure 3b). Furthermore, there was no change in baseline nociception between prenicotine and 8 h postnicotine administration, consistent with the absence of nicotine or nicotine-induced nociception at this time point. Chronic nicotine administration also did not affect morphine analgesia (Figure 3e), indicating a lack of direct effect of nicotine on opioid-induced analgesia *per se*, including on the BBB permeability of morphine. Together, this substantially reduces the likelihood of nicotine pretreatment effects on general nociception, nicotine-mediated analgesia, or opioid-mediated analgesia in this chronic administration paradigm, suggesting instead an effect of nicotine on brain CYP2D levels.

Overall, these results suggest a role of brain CYP2D on codeine metabolism and analgesia. Following codeine administration, analgesia is initially mediated by morphine

formed centrally by brain CYP2D, due to the delay in hepatically formed morphine entering the CNS. Thus lower (or higher) brain CYP2D activity and the consequent decrease (or increase) in brain morphine levels results in lesser (or greater) analgesia during this initial 30 min after codeine injection. Over time, morphine crosses into the brain, suggesting that analgesia at this later time period is mediated by morphine formed by hepatic CYP2D crossing into the CNS (seen from the shift in analgesic peak from morphine (3.5 mg/kg) compared with codeine (20 mg/kg)). The clinical implications of our findings are that individuals with higher brain CYP2D activity, such as genetically ultrarapid CYP2D metabolizers or smokers, may experience a quicker and greater onset of analgesia (and potentially abuse liability) from codeine, whereas those with lower brain CYP2D activity, such as non-smokers or those taking CYP2D inhibitors, may experience a delayed and lower analgesia. Accordingly, our results suggest that a translational study assessing the time course and peak of codeine's analgesic effects in smokers vs non-smokers, or within subject pre-nicotine/postnicotine treatment, would be warranted. Furthermore, it is suggested that drug metabolism within the brain may cause interindividual differences in drug response, which are not reflected in plasma drug levels.

FUNDING AND DISCLOSURE

This work was supported by the Endowed Chair in Addiction for the Department of Psychiatry (to RFT), Canadian Institutes of Health Research (TMD 132557, MOP 97751, and MOP 136937), Centre for Addiction and Mental Health and the CAMH Foundation, the Canada Foundation for Innovation (grant numbers 20289 and 16014), and the Ontario Ministry of Research and Innovation. Dr Rachel F Tyndale has consulted for McNeil and Apotex. Douglas M McMillan has no conflicts of interest to declare.

ACKNOWLEDGMENTS

We would like to thank Dr Sharon Miksys and Dr Bin Zhao for their invaluable technical support and scientific guidance and Fariba Baghai Wadji for her expert assistance with animal procedures.
