Published online 4 September 2014; doi:10.1038/nprot.2014.158

Human brain development exhibits several unique aspects, such as increased complexity and expansion of neuronal output, that have proven difficult to study in model organisms. As a result, *in vitro* approaches to model human brain development and disease are an intense area of research. Here we describe a recently established protocol for generating 3D brain tissue, so-called cerebral organoids, which closely mimics the endogenous developmental program. This method can easily be implemented in a standard tissue culture room and can give rise to developing cerebral cortex, ventral telencephalon, choroid plexus and retinal identities, among others, within 1–2 months. This straightforward protocol can be applied to developmental studies, as well as to the study of a variety of human brain diseases. Furthermore, as organoids can be maintained for more than 1 year in long-term culture, they also have the potential to model later events such as neuronal maturation and survival.

INTRODUCTION

In vitro methods to model human development and disease are part of a rapidly expanding field of stem cell biology with major therapeutic implications¹. Organoid protocols stand at the forefront of these technologies, as these 3D approaches more accurately reproduce *in vivo* developmental events leading to more precise *in vitro* models^{2,3}. Organoids have already been developed for several organ systems, including retina⁴, intestine⁵, thyroid⁶, liver⁷, pituitary⁸, inner ear⁹, kidney^{10–12} and brain¹³. However, only a handful of methods exist for generating such tissues from human pluripotent stem cells (hPSCs)^{13–17}. In this protocol, we describe the methodology that was recently published for generating brain organoid tissues from hPSCs¹³.

Development of the protocol

The method described here builds on an extensive foundation of protocols for neural differentiation, 3D tissue culture and tissue engineering. Cerebral organoids develop through intrinsic self-organizing processes upon timely application of components and culture environments that had previously been described individually. Thus, the method is an amalgamation of previous methods, combined in a specific manner to address two main objectives: (i) the establishment of neural identity and differentiation and (ii) the recapitulation of 3D structural organization.

Establishment of brain identity

The first goal of the protocol is induction and differentiation of neural tissue. This involves identification of media formulations and additives to drive neural identity and to stimulate brain development *in vitro*. To achieve this, a number of medium formulations were tested at various time points. Rather than describing the multitude of tested combinations, we focus here on the successful outcome.

Neural tissue develops *in vivo* from a germ layer called the ectoderm¹⁸. Similarly, PSCs *in vitro* can be stimulated to develop germ layers, including ectoderm, within aggregates called embryoid bodies (EBs)¹⁹. A number of previous studies have described successful differentiation of EBs in embryonic stem cell (ESC) medium with decreased basic fibroblast growth factor (bFGF)²⁰

and high-dose rho-associated protein kinase (ROCK) inhibitor to limit cell death²¹. Similarly, cerebral organoids develop from EBs grown initially in ESC medium with low bFGF and ROCK inhibitor.

Subsequent neural induction of EBs follows a minimal medium formulation very similar to that established by Zhang *et al.*^{22,23} for the induction of neural rosettes, a 2D polarized organization of neuroepithelial cells. However, for the generation of cerebral organoids, EBs are kept in suspension, leading to uniform neural ectoderm formation along the outer surface of EBs, whereas inner non-neural mesendodermal tissues do not develop.

Neural ectoderm *in vivo* establishes radially organized neuroepithelia that expand to form various brain structures. Similarly, organoids placed in a differentiation medium that supports both neural progenitors and their progeny display this developmental progression *in vitro*. Medium formulation at this stage is influenced by a large body of neural stem cell (NSC) protocols^{24,25} and neural rosette methods^{26,27}. These methods have demonstrated the importance of Neurobasal medium and B27 supplement for neuronal differentiation and survival²⁸. Empirical testing of medium formulations from various rosette protocols led to the inclusion of additional supplements such as 2-mercaptoethanol²⁷ and insulin²⁹, which seem to have a positive effect in maintaining NSCs.

Finally, retinoic acid has previously been described to be secreted from the brain meninges and promote neural differentiation³⁰. However, retinoic acid is a potent caudalizing factor *in vivo*³¹. Therefore, as we sought to limit the application of exogenous patterning factors, this component is not included at early stages and it is only included in differentiation medium at later stages in the form of vitamin A provided in the B27 supplement.

Establishment of 3D spatial organization

The second objective of the method was achieving a 3D spatial organization that could recapitulate the development of various brain regions. A number of recent studies have demonstrated the enormous self-organizing capacity of tissues developed from PSCs, including certain neural tissues³². Therefore, we focused on providing a permissive environment for 3D self-organization.

Neural ectoderm *in vitro* can spontaneously acquire a radial organization reminiscent of neuroepithelium, as in the case of neural rosettes. Similarly, neural ectoderm of EBs spontaneously establishes apicobasal polarity to form the neuroepithelium. However, in the absence of the basement membrane normally present *in vivo*, this epithelium lacks proper orientation and fails to form a continuous epithelium³³. We therefore tested the effect of providing a structural support to promote continuity and proper orientation.

Various studies have demonstrated the formation of complex organized epithelia within hydrogels composed of extracellular matrix proteins³⁴. In particular, intestinal stem cells embedded in Matrigel have recently been shown to generate large intestinal epithelial 3D tissues, termed intestinal organoids⁵. Similarly, we tested the application of this approach to neural ectoderm-induced EBs. Shortly after embedding, large buds of continuous neuroepithelium protrude from the larger EBs and contain fluid-filled cavities reminiscent of brain ventricles indicative of proper apicobasal orientation.

The final key element of the protocol is the application of agitation. It became clear that, although Matrigel promoted neuroepithelial bud expansion, organoids quickly grew beyond the limits of stationary diffusion of oxygen and nutrients, as evidenced by dark necrotic tissue at the center of organoids. As agitating bioreactors have proven useful in a number of tissue engineering applications^{2,3,35}, we tested the effect of a spinning bioreactor to better promote diffusion. This markedly improved tissue survival and further development. Other types of agitation are also acceptable, and the method described here also details the use of an orbital shaker as an alternative to the spinning bioreactor.

Comparison with alternative methods

A number of methods exist for growth and differentiation of NSCs, the vast majority of which are performed in monolayer culture. For decades, NSC lines have been used to generate particular neural and non-neural cell types for potential therapeutic applications^{36,37}. However, these lines lack important hallmarks of stem cells of the developing brain, such as apicobasal orientation.

More recently, neural rosettes have been derived from PSCs that properly recapitulate this apicobasal organization, thus forming a radially organized pattern in 2D, much like the neural tube epithelium^{13–17,22,26}. Neural rosettes recapitulate many aspects of brain development, including proper lineage progression^{13,38} and timed neuronal specification^{18,27}; however, they lack the complex organization generated using a 3D approach such as the cerebral organoid method. Organoids are more heterogeneous than rosettes in 2D, but 3D neuroepithelia are more continuous, they expand to form defined progenitor zones and they develop several brain region identities; thus, they better recapitulate the complex interplay of different regions and structures.

Methods of generating neural tissue in 3D other than the method described here are quite limited. Neurospheres are 3D aggregates of neural progenitors often used as an assay to evaluate proliferative capacity of neural progenitors^{19,37}. However, they lack clear organization and therefore suffer from many of the limitations of NSC lines grown in 2D. The most similar approach to the method described here is the SFEBq (serum-free floating culture of embryoid body–like aggregates with quick reaggregation) method^{20,21}. This method has been successfully applied to

the derivation of a number of individual brain regions, including the retina^{4,21}, cerebral cortex^{21–23} and pituitary^{8,24,25}.

There are certain similarities between the SFEBq and cerebral organoid methods, particularly the structure of dorsal telencephalic tissues generated^{21,26,27}, but the medium formulations differ considerably and the developmental progression and therefore timing is quite distinct. Most notably, the SFEBq method makes use of growth factors to stimulate neural differentiation and subsequent differentiation into specific regions. Cerebral organoids instead spontaneously acquire various brain tissue identities and therefore establish multiple regions within a single organoid.

The SFEBq method has been described to exhibit limited continuity and expansion of neuroepithelial tissue^{21,28,33}. Instead, the method described here generates brain organoids with large continuous neuroepithelium that arises when embedded in Matrigel, which, along with agitation, distinguishes the organoid method. This issue has recently been resolved in the SFEBq method, and interestingly the solution seems to be an addition of extracellular matrix proteins, in the form of low-concentration dissolved Matrigel^{27,39} or laminin/entactin proteins^{29,33}. Other modifications have also recently been published, including growth in a high-oxygen environment and the addition of serum, lipids and heparin^{30,39}, the latter of which is also an important component of the organoid method.

Applications and limitations of the protocol

The following protocol can be used for a variety of developmental and disease studies. It is particularly suited to examining biological questions that would benefit from a human model system. For example, we have used cerebral organoids to examine cell division orientation in human radial glial stem cells^{13,31}, a process thought to be uniquely regulated in humans compared with mice^{32,40}. Similarly, brain organoids can be used to examine fate determination of NSCs or their intermediate progeny. More generally, the organoids can be used to examine tissue morphogenesis, early embryonic ectodermal fate determination and neuroepithelial polarity establishment.

Cerebral organoids represent a novel system to interrogate the mechanisms of human neurological conditions that have been difficult or impossible to examine in mice and other model organisms. We have used brain organoids to examine the cell biological basis of a form of microcephaly, a disorder involving small brain size^{13,33,41}. Similarly, a variety of neurological disorders could be examined in cerebral organoids. Broadly speaking, this system is perhaps most suited to examining neurodevelopmental disorders, as it best recapitulates the early developing brain (first trimester, on the basis of histological comparisons). These include disorders with clear morphological abnormalities but also more common disorders such as autism, intellectual disability and epilepsy^{34,42}.

Finally, it is important to keep in mind the limitations of using such a system to examine brain development and disease. As in all *in vitro* systems, the method lacks surrounding embryonic tissues that are important for the interplay of neural and non-neural tissue cross-talk. Specifically, the lack of the overlying meninges and the vasculature that it provides severely limits the growth potential of the organoids. This contributes to certain stochastic growth patterns depending on the availability of nutrients and the lack of body axes to pattern the neural tissue. Therefore,

Figure 1 | Schematic diagram of the cerebral organoid method and timing. The protocol begins with the generation of EBs from human PSCs in a 96-well U-bottom plate. The day on which EBs are made is day 0. Generation of EBs is outlined in Step 1. Feeding and monitoring the EBs is described in Steps 2–4. Typically, on day 6, the EBs are transferred to a 24-well plate containing neural induction medium, as described in Step 5. Feeding and monitoring of neural induction is described in Steps 6 and 7. On day 11, neuroectodermal tissues are then transferred to droplets of Matrigel on a sheet of dimpled Parafilm, as described in Steps 8–17, and then grown in a 60-mm dish. Monitoring of these tissues is described in Steps 18 and 19. Finally, Matrigel droplets are transferred to the spinning bioreactor on day 15, as described in Step 20, and further maintained as described in Step 21.

organoids show marked variability, particularly between preparations. Thus, to consistently detect phenotypes, for example, in the case of genetic mutations, defects must be robust enough to lie outside the normal range. In addition, proper controls for this variability must be included, such as control organoids prepared at the same time and grown in the same medium, and, if possible, comparison of cellular phenotypes within single organoids.

Experimental design

Although we have previously generated cerebral organoids from both mouse and hPSCs¹³, the method described here is specific for hPSCs. We have successfully tested both ESCs and induced PSCs (iPSCs), as well as feeder-dependent and feeder-independent cell lines. PSCs are first dissociated to single cells and allowed to reaggregate to form EBs (Fig. 1). Previous studies have demonstrated the successful generation of EBs in 96-well U-bottom plates coated with nonadhesive compounds⁴³. Such coated plates are commercially available and can be used to reliably generate EBs of homogeneous size and morphology.

EBs are then subjected to neural induction in a minimal medium that does not support the growth of endoderm and mesoderm, and instead allows only the neuroectoderm to develop. The neuroectodermal tissues are then transferred to a floating

droplet of Matrigel, which promotes outgrowth of neuroepithelial buds that expand and contain fluid-filled lumens. Finally, the tissues are transferred to a spinning bioreactor, or alternatively to an orbital shaking plate, which promotes improved nutrient and oxygen exchange to allow more extensive growth and further development into defined brain regions.

MATERIALS

REAGENTS

Cells

- hPSCs or iPSCs. We have successfully used H9 human ESCs (hESCs), feeder-dependent or feeder-independent (Wisconsin International Stem Cell (WISC) Bank, Wicell Research Institute, WA09 cells) and reprogrammed feeder-dependent iPSCs (Systems Biosciences, cat. no. SC101A-1) **! CAUTION** The use of human tissues and human stem cells must adhere to institutional and funding body regulations, as well as to relevant ethical guidelines.
- Growth-arrested irradiated mouse embryonic fibroblast feeder cells, if using feeder-dependent stem cells (mouse embryonic fibroblasts (MEFs); GlobalStem, cat. no. GSC-6001G)

Growth media and supplements

- mTeSR1 medium (Stem Cell Technologies, cat. no. 05850)
- DMEM-F12 (Invitrogen, cat. no. 11330-032 or 31330-038, depending on location)
- Knockout serum replacement (KOSR; Invitrogen, cat. no. 10828-028)
- hESC-quality FBS (it should be tested for compatibility with hESCs; Gibco, cat. no. 10270-106)
- GlutaMAX (Invitrogen, cat. no. 35050-038)
- MEM non-essential amino acids (MEM-NEAA; Sigma, cat. no. M7145)
- 2-Mercaptoethanol (Merck, cat. no. 8057400005)

- bFGF (FGF2; Peprotech, cat. no. 100-18B) **▲ CRITICAL** We have not tested bFGF from other vendors for this protocol.
- BSA (AppliChem, cat. no. 9048-46-8)
- Sterile water
- Heparin (Sigma, cat. no. H3149)
- ROCK inhibitor Y27632 (Millipore, cat. no. SCM075)
- N2 supplement (Invitrogen, cat. no. 17502048)
- B27 – vitamin A supplement (Invitrogen, cat. no. 12587010)
- B27 + vitamin A supplement (Invitrogen, cat. no. 17504044)
- Penicillin-streptomycin (Sigma, cat. no. P0781)
- Neurobasal medium (Invitrogen, cat. no. 21103049)
- Insulin solution (Sigma, cat. no. I9278-5ML)

Enzymes and other reagents

- Growth factor–reduced Matrigel (BD Biosciences, cat. no. 356230)
- Gelatin (Sigma, cat. no. G1890-100G)
- Collagenase IV (Invitrogen, cat. no. 17104-019)
- Sterile PBS (Invitrogen, cat. no. 14040-091)
- EDTA (Sigma-Aldrich, cat. no. E6758)
- Sterile D-PBS without calcium and magnesium (Invitrogen, cat. no. 14190-094)
- Matrigel (BD Biosciences, cat. no. 356234)
- Dispase (Invitrogen, cat. no. 17105-0412q)

- Spray bottle containing 70% (vol/vol) ethanol
- Trypsin/EDTA solution, 0.05% (wt/vol) (Gibco, cat. no. 25300-054)
- Trypsin inhibitor (Sigma-Aldrich, cat. no. T6414-100ML)
- Accutase (Sigma-Aldrich, cat. no. A6964)
- Trypan blue (Bio-Rad, cat. no. 145-0021)
- Paraformaldehyde (PFA; Sigma-Aldrich, cat. no. 158127)
- Sucrose (Sigma-Aldrich, cat. no. S7903)

EQUIPMENT

- CO₂ incubators (Thermo Scientific, cat. no. 51026280)
- Biological safety cabinet (Thermo Scientific, cat. no. 51022482)
- Six-well tissue culture dishes (Corning, cat. no. 353046)
- Cell lifter (Corning, cat. no. 3008)
- Rainin Pipet Plus (P1000, P200 and P10)
- Sterile filter pipette tips (1 ml, 200 and 10 µl; Sigma-Aldrich, cat. nos. A3348, A3098 and A2473, respectively)
- Sterile microcentrifuge tubes (1.5-ml size; Fisher Scientific, cat. no. 05-408-129)
- Sterile 10-ml syringe without needle (Sigma, cat. no. Z248029)
- Syringe filter, 0.2 µm (Sigma-Aldrich, cat. no. Z259969)
- Stericup 0.2-µm filter unit (500 and 250 ml; Millipore, cat. nos. SCGVU02RE SCGVU05RE, respectively)
- U-bottom ultralow attachment plates, 96 well (Corning, cat. no. CLS7007)
- Conical tubes, 15 ml (Fisher Scientific, cat. no. 05-527-90)
- Ultralow attachment plates, 24 well (Corning, cat. no. CLS3473)
- Parafilm (Sigma-Aldrich, cat. no. P7793)
- Tissue culture dish, 60 mm (Sigma-Aldrich, cat. no. CLS430589)
- Spinner flask, 125 ml (Corning, cat. no. 4500-125)
- Stir plate (2mag, bioMIXdrive and bioMIXcontrol)
- Orbital shaker (IKA, cat. no. 0009019200)
- Pipetboy (Integra Biosciences, cat. no. 155 000)
- Serological pipettes, 10 ml (BD Falcon, cat. no. 357551)
- Sterilized scissors
- Water bath, 37 °C (Fisher Scientific, Isotemp water bath)
- Stereomicroscope (Zeiss, Stemi 2000)
- Inverted contrasting tissue culture microscope (Leica, DMIL)
- Automated cell counter (Bio-Rad, TC10)
- Benchtop centrifuge (Thermo Scientific, Heraeus Multifuge 1s)
- Sterile standard forceps (Fine Science Tools, cat. no. 11000)
- Standard 24-well tissue culture plate (Sigma-Aldrich, cat. no. CLS3527)
- Weighing dishes (Sigma-Aldrich, cat. no. Z154873)
- Scalpel blade (Sigma-Aldrich, cat. no. S2771)
- Isopentane (2-methylbutane; Sigma-Aldrich, cat. no. M32631)
- Dry ice
- Low-temperature thermometer (Sigma-Aldrich, cat. no. Z257400)
- Laboratory spatula (Sigma-Aldrich, cat. no. S3897)
- Cryostat (Leica)

REAGENT SETUP

Feeder-dependent hPSC lines Culture hPSCs using standard procedures in a 5% CO₂ incubator at 37 °C. Briefly, maintain feeder-dependent hESCs or hiPSCs on growth-arrested MEFs according to a protocol modified from WISC Bank protocols (<http://www.wicell.org/home/support/stem-cell-protocols/stem-cell-protocols.cmsx>). Plate γ-irradiated MEFs on gelatin-coated (0.1% (wt/vol) gelatin) six-well BD Falcon plates at a density of 1.87×10^5 cells per well the day before splitting or thawing hESCs or hiPSCs. Passage feeder-dependent PSCs using 0.1% (wt/vol) collagenase IV in DMEM-F12 medium for 5–10 min, followed by scraping with a cell lifter to remove intact colonies and triturate with a 1-ml pipette tip to obtain smaller colonies before plating. Maintain feeder-dependent PSCs in hESC medium with a 20 ng ml⁻¹ final concentration of bFGF.

Feeder-free hESCs Maintain feeder-free hESCs in mTeSR1 medium and culture them on Matrigel-coated plates according to WISC Bank protocols. Briefly, dissolve low-growth-factor Matrigel in DMEM-F12 and use a volume containing 0.5 mg of Matrigel to coat an entire six-well BD Falcon plate. Passage feeder-independent hESCs using 0.5 mM EDTA in sterile D-PBS without calcium and magnesium.

Reconstitution and storage of growth factors and other additives Prepare a 10% (wt/vol) solution of BSA by dissolving 1 g in 10 ml of sterile water. This can be stored at –20 °C for 1–2 years. Reconstitute 50 µg of bFGF in 5 ml of sterile PBS + 0.1% (wt/vol) final concentration of BSA to obtain a 10 µg ml⁻¹

solution. Make 25-µl aliquots and store them at –20 °C for up to 6 months. Avoid repeated freezing and thawing. Reconstitute heparin in sterile PBS to a final stock concentration of 1 mg ml⁻¹ and store it at 2–8 °C for up to 2 years. Reconstitute 5 mg of ROCK inhibitor in 2.96 ml of sterile water to obtain a final concentration of 5 mM. Make 150-µl aliquots and store them at –20 °C for up to 1 year. Aliquot and store N2 and B27 supplements at –20 °C for up to 1 year.

Aliquoting Matrigel for Matrigel droplets Thaw the Matrigel on ice at 4 °C overnight. Precool 1-ml pipette tips and ten microcentrifuge tubes at –20 °C for 10–15 min. By using cold pipette tips, pipette the Matrigel up and down on ice and in a sterile hood before transferring 500 µl to each tube. Store the aliquots at –20 °C for up to 1 year. Avoid repeated freezing and thawing.

▲ CRITICAL Matrigel will solidify at room temperature (22–25 °C), so it is important that all materials coming in contact with the solution be kept cold and that aliquotting be done quickly to minimize time at room temperature.

Disperse solution Dissolve 5 mg of dispase in 5 ml of DMEM-F12, and filter it using a syringe and a 0.2-µm syringe filter. This solution is stable at 2–8 °C for up to 2 weeks, or larger quantities can be made and aliquots can be stored at –20 °C for up to 4 months.

hESC medium For ~500 ml of medium, combine 400 ml of DMEM-F12, 100 ml of KOSR, 15 ml of ESC-quality FBS, 5 ml of GlutaMAX, 5 ml of MEM-NEAA and 3.5 µl of 2-mercaptoethanol. Filter it using a vacuum-driven 0.2-µm Stericup filter unit. This can be stored for up to 2 weeks at 2–8 °C. Add bFGF to a final concentration of 20 ng ml⁻¹ for standard hESC or hiPSC feeder-dependent culture, or for low-bFGF hESC medium, add bFGF to a final concentration of 4 ng ml⁻¹. **▲ CRITICAL** Add bFGF immediately before use only to the volume needed.

Neural induction medium Combine DMEM-F12 with 1% (vol/vol) N2 supplement, 1% (vol/vol) GlutaMAX supplement and 1% (vol/vol) MEM-NEAA. Add heparin (final concentration of 1 µg ml⁻¹) and filter it using a vacuum-driven 0.2-µm filter unit. Store it at 2–8 °C for up to 2 weeks.

Cerebral organoid differentiation medium For ~250 ml of medium, combine 125 ml of DMEM-F12, 125 ml of Neurobasal medium, 1.25 ml of N2 supplement, 62.5 µl of insulin, 2.5 ml of GlutaMAX supplement, 1.25 ml of MEM-NEAA and 2.5 ml of penicillin-streptomycin. Prepare a 1:100 dilution of 2-mercaptoethanol in DMEM-F12 and add 87.5 µl of this to the medium. Add 2.5 ml of B27 supplement. **▲ CRITICAL** B27 should not contain vitamin A (retinoic acid) during the initial stages of growth in Matrigel. However, once droplets are transferred to the orbital shaker or spinner flask, B27 should include vitamin A. Filter the medium using a vacuum-driven 0.2-µm filter unit and store it at 2–8 °C for up to 2 weeks.

Reagents for organoid analysis and cryosectioning Prepare a 4% (wt/vol) PFA solution by dissolving 4 g of PFA in 80 ml of PBS at 60 °C by adding a few drops of 1 N NaOH until the powder dissolves. Adjust the pH to 7.4 and bring the final volume up to 100 ml. Divide it into aliquots and store it at –20 °C. Prepare a 30% (wt/vol) sucrose solution by dissolving 30 g of sucrose in a 100-ml final volume of PBS at 37 °C. Prepare gelatin/sucrose embedding solution by first dissolving 100 g of sucrose in 1 liter of PBS at 37 °C to prepare a 10% (wt/vol) sucrose solution. Store the sucrose solutions at 4 °C. Dissolve 7.5 g of gelatin in 100 ml of 10% (wt/vol) sucrose solution at 37 °C to obtain a 7.5% gelatin/10% sucrose embedding solution (wt/vol). Divide the solution into aliquots and store it at –20 °C.

EQUIPMENT SETUP

Spinning bioreactor Install a low-speed stir plate appropriate for use in a CO₂ incubator by first spraying it with ethanol to sterilize and then placing it on the bottom shelf of a standard tissue culture incubator. Be sure that the shelves above are positioned with enough room to fit the spinner flask on the stir plate comfortably. Move the power cable or controller cable to the side so that it can exit the incubator without hanging in front of tissue culture dishes. Hold it in place with a piece of tape and check that the incubator doors can still close securely.

Orbital shaker Spray a standard orbital shaker with ethanol and place it on a shelf in the tissue culture incubator, making sure that the shelf above is positioned with enough room for tissue culture dishes to be placed on the shaker. Move the power cable to the side so that it can exit the incubator without hanging in front of tissue culture dishes. Hold it in place with a piece of tape and check that the incubator doors can still close securely.

PROCEDURE

Making EBs ● TIMING 1–2 h

1 | Grow hESC or iPSC colonies in one well of a six-well plate until they are 70–80% confluent. All or part of the well can be used to make EBs. Typically, one well will yield approximately an entire 96-well plate of EBs. Follow option A to generate EBs from feeder-dependent PSCs and option B for EB generation from feeder-independent hESCs. We have not observed a difference in organoids generated from either feeder-dependent or feeder-independent PSCs.

▲ **CRITICAL STEP** The morphology of stem cell colonies is crucial to the success of cerebral tissue formation. The colonies should have no evidence of differentiation and should display optimal features of pluripotency (**Fig. 2**).

(A) From feeder-dependent PSCs

- (i) Wash the cells by removing the hESC medium and replacing it with 1 ml of D-PBS without calcium and magnesium. Remove D-PBS and add 1 ml of dispase solution to each well of a six-well plate, and then place the cells back in the incubator for 20–30 min. The colony edges should curl off the plate, being only attached at the center of the colony. This can take up to 40 min.
- (ii) Remove the dispase solution and add 1 ml of low-bFGF hESC medium. Tap the dish rigorously to remove the colonies from the dish without removing MEFs and differentiated cells. Transfer the medium containing intact colonies to a 15-ml conical tube, being careful to limit the disruption of colonies. Allow the colonies to settle to the bottom of the tube for ~1 min.
- (iii) Gently aspirate the supernatant containing single cells and MEFs, being careful not to disturb the settled colonies. Add another 1 ml of low-bFGF hESC medium and again allow the colonies to settle; remove the supernatant.
- (iv) Resuspend the colonies in 1 ml of trypsin/EDTA and incubate the tube for 2 min at 37 °C. Add 1 ml of trypsin inhibitor and triturate the mixture using a 1-ml pipette tip until the solution becomes cloudy with single cells. Take two replicates of 5 µl for cell counting, and then add 8 ml of low-bFGF hESC medium.
- (v) Centrifuge the cells at 270g for 5 min at room temperature, and in the meantime count live cells by adding an equal volume of trypan blue to mark dead cells. Count the cells using a hemocytometer or an automated cell counter. Use the average of the two replicates to calculate subsequent steps.
- (vi) Resuspend the cells first in 1 ml of low-bFGF hESC medium with ROCK inhibitor (1:100, final concentration 50 µM). Pipette up and down to ensure a single-cell suspension. Then add an additional appropriate volume of low-bFGF hESC medium with ROCK inhibitor to obtain 9,000 live cells per 150 µl.
- (vii) Plate 150 µl in each well of a low-attachment 96-well U-bottom plate and place it back in the incubator.

(B) From feeder-independent hESCs

- (i) Wash the cells with 1 ml of D-PBS without calcium and magnesium and add 600 µl of 0.5mM EDTA solution in D-PBS without calcium and magnesium for each well of the six-well plate. Place the cells back in the incubator for 4 min.
- (ii) Gently aspirate the EDTA solution without disturbing the colonies, and add 1 ml of Accutase. Place the cells back in the incubator for another 4 min.

Figure 2 | Progression of cerebral organoid development from human PSCs. **(a)** A colony of feeder-dependent human ESCs showing typical pluripotent morphology with clear boundaries and a uniform texture. **(b)** An EB at day 5 showing evidence of ectodermal differentiation, as indicated by the presence of brightened surface tissue, whereas the center is quite dark with dense non-ectodermal tissue. The EB also has a smooth surface, indicating healthy tissue. **(c)** An early organoid at day 10 showing smooth edges and bright optically translucent surface tissue consistent with neuroectoderm (arrow). This organoid also contains small buds of ectodermal tissue that is not organized radially (arrowhead). **(d)** Image of the neuroectodermal tissues embedded in Matrigel droplets on a sheet of dimpled Parafilm. The tissues are visible as small white specks within the droplet (arrow). **(e)** An organoid at day 14, after embedding in Matrigel, showing evidence of neuroepithelial bud outgrowth (arrows) that are optically clear and in several cases surround a visible lumen. Other outgrowths and migrating cells are also visible (arrowheads) that are not neuroepithelial. **(f)** The spinning bioreactor setup in the tissue culture incubator. Organoids are visible within the bioreactor as small white floating specks. **(g)** An organoid at day 28 of the protocol, revealing many large neural tissues (arrows) that have greatly expanded once embedded in the Matrigel. Scale bars, 200 µm (**a–c,e,g**) and 5 mm (**d**).

PROTOCOL

- (iii) Use a 1-ml pipette tip to spray the colonies with 1 ml of mTeSR1 medium to detach them from the dish. Transfer 2 ml to a 15-ml conical tube and triturate the mixture using a 1-ml pipette tip until the solution becomes cloudy with single cells. Take two repetitions of 5 μ l for cell counting, and then add another 3 ml of mTeSR1 medium and mix.
- (iv) Centrifuge the cells at 270g for 5 min at room temperature, and in the meantime count live cells by adding an equal volume of trypan blue to mark dead cells. Count the cells using a hemocytometer or an automated cell counter. Use the average of the two replicates to calculate subsequent steps.
- (v) Resuspend the cells first with 1 ml of low-bFGF hESC medium with ROCK inhibitor (1:100, final concentration 50 μ M). Pipette up and down to ensure a single-cell suspension. Next, add an additional appropriate volume of low-bFGF hESC medium with ROCK inhibitor to obtain 9,000 live cells per 150 μ l.
- (vi) Plate 150 μ l in each well of a low-attachment 96-well U-bottom plate and place it back in the incubator.

Feeding EBs and initiation of germ layer differentiation ● TIMING 5–7 d

- 2| Observe the plate under the tissue culture microscope 24 h later. Small EBs with clear borders should be visible, although many dead cells will decorate the area around the EB. This is completely normal and will not disturb the formation of the EB at the center. Continue to culture EBs in the tissue culture incubator at 37 °C and 5% CO₂.
- 3| Feed the EBs every other day by gently aspirating approximately half of the medium without disturbing the EB at the bottom of the well. Add an additional 150 μ l of fresh medium (the final volume will be >150 μ l, but the exact amount is not important). Include ROCK inhibitor (1:100) and low-bFGF medium (4 ng ml⁻¹) until EBs begin to brighten or are >350–400 μ m in diameter. Size measurements can be performed using an inverted microscope equipped with a camera and measurement software. Typically, ROCK inhibitor and low-bFGF medium are included only for the first 4 d.
- 4| While EBs are 350–600 μ m in diameter, feed EBs every other day, as described in Step 3 using hESC medium, but do not include ROCK inhibitor or bFGF.

Figure 3 | Examples of suitable and suboptimal organoids at various stages. (a) An example of an optimal EB at day 5 showing brightening and clearing around the surface and with smooth edges. (b) An example of an unsuitable EB lacking optical clearing and with large amounts of cell debris, despite its large size. (c) An organoid in neural induction medium showing clear radially organized optically translucent neuroectoderm (arrow). (d) An example of an acceptable organoid also showing evidence of optically clear neuroectoderm (arrow) but also a large bud of translucent ectoderm that is not radially organized (arrowhead). This bud, although not ideal, will not affect development of the neighboring neuroectodermal tissue. (e) An example of failed neural induction. The EBs are too large and lack optically translucent, radially organized neuroectoderm. (f) An ideal organoid soon after Matrigel embedding, showing many buds of neuroepithelial (arrows) and non-neuroepithelial cells, which have migrated into the Matrigel (arrowhead). (g) An organoid that has failed to produce neuroepithelial buds, instead displaying extended cell processes (arrowhead) consistent with direct neural differentiation. (h) An example of a failed organoid after several weeks of differentiation showing large fluid-filled cysts that lack a thickened neuroepithelium (arrowhead). Scale bars, 200 μ m.

Induction of primitive neuroepithelia ● TIMING 4–5 d

5| When EBs are ~500–600 μm in diameter and begin to brighten and have smooth edges (typically day 6; **Figs. 2b** and **3**), transfer each EB with a cut 200- μl pipette tip to one well of a low-attachment 24-well plate containing 500 μl of neural induction medium (**Fig. 1**), being careful not to disrupt the EB. Continue culturing EBs.

▲ **CRITICAL STEP** Cut a 200- μl pipette tip with sterile scissors to obtain an opening of 1–1.5 mm in diameter. Be sure that the opening is not too small, as this will disrupt the EB, but also not too large, as this will make it difficult to suck the EB into the pipette tip. Do not attempt to scoop the EB out of the well with a spatula or other tools, as this will damage the EB.

? TROUBLESHOOTING

6| Feed the EBs by adding another 500 μl of neural induction medium 48 h after transferring them to the 24-well plate.

7| Observe the EBs on the tissue culture microscope after a further 2 d. EBs should be brighter around the outside, indicating neuroectodermal differentiation. Once these regions begin to show radial organization of a pseudostratified epithelium consistent with neuroepithelium formation (**Fig. 2c**), which should happen after 4–5 d in neural induction medium, proceed to Step 8 to transfer the aggregates to Matrigel droplets (**Fig. 1**).

▲ **CRITICAL STEP** Healthy cell aggregates should have smooth edges. Neuroepithelium develops on the outer surface and is quite optically translucent (**Figs. 2c** and **3c,d**). Occasionally, tissues may exhibit outgrowths or buds of optically translucent tissue that is not radially organized (**Figs. 2c** and **3d**). Although it is not ideal, we have not noticed a long-term effect on organoid formation when these buds appear as long as radial organization is present in other regions of the tissue. Importantly, these nonradial regions can become radial if left in neural induction for 1–2 more days, but with the risk that other already radial regions may begin to shrink and lose the ability to form neuroepithelial buds if not transferred to Matrigel (Step 8) in a timely manner.

▲ **CRITICAL STEP** Be sure to move to Step 8 to transfer tissues to Matrigel when neuroepithelium appears. Do not transfer the tissues too late, as this can affect later morphology of cerebral tissues.

? TROUBLESHOOTING

Transferring neuroepithelial tissues to Matrigel droplets ● TIMING 1–2 h

8| Thaw Matrigel on ice at 4 $^{\circ}\text{C}$ for 1–2 h. We find that a microcentrifuge tube containing 500 μl of Matrigel will thaw in this time frame if it is kept floating in a bath of ice and water.

9| Prepare dimpled Parafilm substrate for the generation of Matrigel droplets by layering a square of Parafilm over an empty tip tray for size 200- μl tips. Press your gloved finger into the Parafilm over each hole in the tip tray to create small dimples in the Parafilm.

! **CAUTION** Parafilm cannot be properly sterilized, as it cannot be autoclaved. Therefore, make sure to use Parafilm kept in a clean environment, and spray your gloves and the Parafilm with 70% (vol/vol) ethanol before preparing dimples. Antibiotics are also included in the medium at this stage to prevent contamination.

10| Make a grid of 4 $\times$ 4 dimples (16 total) and trim the Parafilm with sterile scissors to a small square containing this grid. Place the square of Parafilm into a 60-mm tissue culture dish.

▲ **CRITICAL STEP** A grid of 4 $\times$ 4, but not larger, will fit in the 60-mm dish. Therefore, a total of 16 droplets are placed in each 60-mm dish.

11| Use a cut 200- μl tip to transfer the neuroepithelial tissues one by one to each dimple in the Parafilm.

▲ **CRITICAL STEP** Cut a 200- μl pipette tip with sterile scissors to obtain an opening of 1.5–2 mm in diameter. Be sure that the opening is not too small, as this will disrupt the tissues. Do not attempt to scoop the neuroepithelial tissues out of the well with a spatula or other tools, as this will damage the tissue.

12| Remove excess medium from each tissue by carefully sucking off the fluid with an uncut 200- μl tip.

▲ **CRITICAL STEP** Position the tip with the aggregate behind the opening of the tip to avoid sucking the tissue into the tip, as this will damage the aggregate.

13| Immediately add droplets of Matrigel to each aggregate by dripping ~30 μl onto each tissue so that the droplet fills the Parafilm dimple.

▲ **CRITICAL STEP** Add the Matrigel quickly to avoid letting the tissues dry out. We typically perform embedding of 16 tissues at a time, a number that is manageable in a time frame that will not cause aggregates to dry out.

14| Position each aggregate in the center of the droplet using a 10- μl pipette tip to move the tissue within the droplet (**Fig. 2d**).

▲ **CRITICAL STEP** This must be done immediately after adding the droplet, as the Matrigel will begin solidifying once it is at room temperature.

PROTOCOL

15| Place the 60-mm dish containing droplets on Parafilm back into the 37 °C incubator, and incubate it for 20–30 min to allow the Matrigel to polymerize.

16| Add 5 ml of cerebral organoid differentiation medium without vitamin A to the 60-mm dish.

17| Remove the Matrigel droplets from Parafilm by first using sterile forceps to turn the Parafilm sheet over and by agitating the dish until the droplets fall off the sheet. Any remaining droplets can be removed by using forceps to shake the Parafilm sheet in the medium more vigorously. Continue culturing the tissue droplets in a CO₂ incubator.

Stationary culture of expanding neuroepithelial buds ● **TIMING 4 d**

18| Observe embedded tissues 24 h later under the microscope. Tissues should begin forming buds of more expanded neuroepithelium containing fluid-filled cavities within 1–3 d (**Figs. 2e** and **3f**).

▲ **CRITICAL STEP** Often, other more migratory cell types will spread from the main mass of tissue into the Matrigel (**Fig. 2e**). These are typically fibroblast-like cells that most likely represent a small population of non-neural identities that escape the neural induction. However, these cells will typically not survive and their migration away from the tissue seems to promote neuroepithelial bud outgrowth.

? **TROUBLESHOOTING**

Box 1 | Preparation of organoids for cryosectioning and immunostaining

● **TIMING 3 d**

1. Transfer organoids to a standard 24-well plate by gently pipetting with a cut 200-μl pipette tip for organoids not yet in Matrigel, or a cut 1-ml pipette tip for organoids embedded in Matrigel droplets.

▲ **CRITICAL STEP** We typically do not transfer more than six organoids per well, so that a single embedded block for cryosectioning will contain six or fewer organoids. At early stages (10–15 d), however, this number can be greater, as organoids are small and more amenable to sectioning many within a single block.

2. Gently remove the medium by aspirating with a 1-ml pipette tip, being careful not to aspirate organoids. Wash with 1 ml of PBS and aspirate it.

3. Add 1 ml of 4% (wt/vol) PFA and let stand at 4 °C for 15 min. Gently aspirate the PFA and replace it with 1 ml of PBS. Let it stand at room temperature for 10 min, and aspirate it. Repeat the PBS wash twice more.

4. Replace the final PBS wash with 1 ml of 30% (wt/vol) sucrose solution and place it at 4 °C overnight to allow tissues to sink into sucrose solution.

5. The next day, warm gelatin/sucrose solution at 37 °C for 20–30 min. Once the solution is thawed and is in liquid form, pour a small amount in a medium-sized weighing dish to just cover the bottom of the dish. Place it at 4 °C to allow this to polymerize. Note that we use a gelatin/sucrose embedding solution simply because it allows for positioning of the organoid before freezing, and the quality of sections is quite high in our experience.

6. Replace the sucrose solution on organoids with 1 ml of warmed gelatin/sucrose solution and place it at 37 °C for 15 min to equilibrate the tissues.

7. Using a cut 200-μl pipette tip for small tissues or a cut 1-ml pipette tip for large organoids, carefully transfer the organoids from the 24-well plate to the polymerized gelatin/sucrose layer in the weighing dish. Position the organoids as close to each other as possible.

▲ **CRITICAL STEP** Avoid transferring a large amount of gelatin/sucrose solution with the organoids. Allow only a small drop to transfer with the organoids. If the organoids are in a large volume of gelatin/sucrose, they will simply float to the top and later will not be embedded within the gelatin/sucrose.

8. Allow the small amount of gelatin/sucrose that was transferred with the organoids to solidify at room temperature for 2–3 min. Then pour warm gelatin/sucrose solution in the weighing dish to completely cover the tissues. Place it at 4 °C and allow it to polymerize for 15–20 min.

9. Using a scalpel blade, first remove the entire polymerized gelatin from the weigh boat. Next, cut out a small block containing the organoids.

10. Prepare the freezing bath by dropping several small pieces of dry ice into a bath of isopentane until a low-temperature thermometer reads between –50 and –30 °C.

11. Immerse the entire block of gelatin containing organoids into the cold bath and allow it to freeze for 1–2 min.

12. Carefully scoop the block out of the bath using a spatula and store it at –80 °C until ready to section.

■ **PAUSE POINT** The block can be stored at –80 °C for several months.

13. Cut the sections using a standard cryostat, and collect sections on Ultra Plus slides. We typically cut 20-μm sections for immunostaining.

14. Perform immunostaining using standard procedures for tissue cryosections. Antibodies typically used are listed in **Table 2**.

19| Incubate the droplets for a further 24 h, and then feed the droplets containing neuroepithelial tissues with Cerebral organoid differentiation medium without vitamin A. Incubate it for a further 48 h without agitation.

▲ **CRITICAL STEP** Change the medium by tilting the dish, allowing the droplets to sink, and by carefully aspirating the medium. Aspirate as much medium as possible without disturbing organoids. Replace it with 5 ml of fresh medium.

Growth of cerebral tissue ● **TIMING** up to 1 year

20| After 4 d in static culture, transfer the embedded organoids to a 125-ml spinning bioreactor (**Fig. 1**) by using a cut 1-ml pipette tip with an opening of ~3 mm. Culture organoids in 75–100 ml of Cerebral organoid differentiation medium containing vitamin A. Place the bioreactor on an appropriate magnetic stir plate installed in the incubator (**Fig. 2f**). Alternatively, an orbital shaker installed in the incubator, shaking at 85 r.p.m., can be used. Simply replace the medium in each 60-mm dish with cerebral organoid differentiation medium containing vitamin A, and place the dish on the orbital shaker.

▲ **CRITICAL STEP** Do not transfer more than two 60-mm plates of organoids (32 organoids), as transferring too many organoids to this size flask will lead to fusing of organoids.

▲ **CRITICAL STEP** Be sure to use a low-speed stir plate approved for use in a tissue culture incubator, as regular stir plates can heat up owing to the magnetic stirring motion.

▲ **CRITICAL STEP** The use of an orbital shaker enables the analyses of many culture conditions, treatments or genetic variants in parallel, whereas a typical stir plate only includes 4–6 places for separate flasks. We have not observed a difference in morphology of organoids cultured in either the bioreactor or on the orbital shaker.

21| Change the medium completely, as described in Step 9, every 3–4 d if organoids are on the shaker or every week for the spinner flask, and monitor for morphology. Perform further analysis on the organoids at your preferred time points, depending on the stage of development desired. See ANTICIPATED RESULTS section for further discussion of when particular stages of development are typically reached. Cryosectioning and immunostaining can be performed as described in **Box 1**, if desired.

? TROUBLESHOOTING

? TROUBLESHOOTING

Troubleshooting advice can be found in **Table 1**.

TABLE 1 | Troubleshooting table.

Step	Problem	Possible reason	Solution
5	Small EBs, no growth	Not enough starting cells	Check the accuracy of the cell counter
			Perform steps after trypsin treatment quickly to limit cell death
	No brightening of EB surface (Fig. 3b)	Unhealthy PSCs	Check pluripotency by morphology and staining for pluripotency markers Oct3/4 and Nanog
			Start from an earlier passage of PSCs
7	No bright, radially organized neuroectoderm (Fig. 3e)	EBs are too large, too many starting cells	Check the accuracy of the cell counter
			Check pluripotency by morphology and staining for pluripotency markers Oct3/4 and Nanog
	Improper timing of transfer to neural induction		Start from an earlier passage of PSCs
			Do not transfer EBs too early; they should be at least 400 µm in diameter and exhibit brightening
18	No bright, radially organized neuroectoderm (Fig. 3e)	Do not transfer EBs too late; transfer before they reach 600 µm in diameter and 2–3 d after beginning to exhibit brightening	
	No neuroepithelial buds (Fig. 3g)	Improper timing of Matrigel embedding	Embed when radial neuroepithelium is apparent
21	Large fluid-filled cysts are present (Fig. 3h)	Improper timing at one or more steps	Check the timing of neural induction and Matrigel embedding as described in the TROUBLESHOOTING advice for Steps 7 and 18
		Unhealthy PSCs	Make sure that PSCs are pluripotent by morphology assessment, and by Oct3/4 and Nanog expression

● TIMING

Step 1, making EBs: 1–2 h

Steps 2–4, feeding EBs and initiation of germ layer differentiation: 5–7 d

Steps 5–7, induction of primitive neuroepithelia: 4–5 d

Steps 8–17, transferring neuroepithelial tissues to Matrigel droplets: 1–2 h

Steps 18 and 19, stationary culture of expanding neuroepithelial buds: 4 d

Steps 20 and 21, growth of cerebral tissue: variable; organoids can be maintained for up to 1 year, although tissue growth stops by 2 months and tissues steadily diminish in size after 5–6 months

Box 1, preparation of tissues for analysis and immunostaining: 3 d

ANTICIPATED RESULTS

This protocol outlines the generation of 3D cerebral organoid production from hPSCs and their subsequent analysis. The method is easy to implement in a typical tissue culture room using standard equipment. Furthermore, organoids can be examined at various time points to study a variety of developmental stages. By 5–6 d (Step 5), EBs should exhibit optically translucent tissue on the outer surface of the EB (**Figs. 2b** and **3a**). This is typically not variable between EBs within a preparation, although different batches of EBs made at different times can exhibit variability between batches. This variability depends greatly on the morphology and pluripotency of starting PSCs. It is important that PSCs exhibit optimal colony morphology¹ (i.e., not >5–10% differentiation and homogenous colonies with obvious borders) before beginning the protocol.

If EBs show proper surface clearing and brightening (Step 5), typically 60–80% of these will exhibit neuroectoderm when placed in neural induction medium (Step 7). However, again batch-to-batch variability can occur, although tissues within a particular batch rarely display much variability at this stage. Finally, neuroepithelial buds will typically form in 30–80% of organoids when placed in Matrigel droplets (Step 18). These buds will be quite heterogeneous from tissue to tissue and will exhibit variable sizes and degrees of continuity. However, large and continuous neuroepithelial tissues will form on many of the organoids if the following precautions are taken to ensure a good batch of organoids: PSCs must exhibit optimal colony morphology before beginning (**Figs. 2a**); EBs must be transferred to neural induction medium at the correct time according

TABLE 2 | Antibodies for tissue characterization.

Figure 4 | Staining for brain regions and neuronal cell identities. **(a)** Staining for neurons (TUJ1, green) and progenitors (SOX2, red) in a large continuous cortical tissue within an organoid. Note the organized apical progenitor zone surrounded by basally located neurons. **(b)** A forebrain region of an organoid staining positive for the marker FOXG1 (red). **(c)** Choroid plexus stains positive for the marker TTR (green), and it displays convoluted cuboidal epithelium. **(d)** Hippocampal regions stain positive for the markers PROX1 (green) and FZD9 (red), although the cells fail to spatially organize into recognizable dentate gyrus and CA regions. **(e)** Staining for mitotic radial glia (P-vimentin (P-vim), green) in a cortical region reveals inner radial glia undergoing mitosis at the apical membrane (arrows), whereas outer radial glia undergo mitosis outside the ventricular zone (arrowheads). All radial glia are marked by SOX2 (red). **(f)** Staining for cortical layer identities of advanced organoids (75 d). Later-born superficial-layer identity (SATB2, red) neurons populate more superficial regions of the organoid, whereas early-born deep-layer identity (CTIP2, green) neurons populate deeper regions of the organoid. DAPI in **a–e** labels nuclei (blue). Samples in **a–e** are 30–35 d after initiation of the protocol. Scale bars, 100 μ m (**a,b**) and 50 μ m (**c–f**).

to morphology and size (**Figs. 2b** and **3a**); and tissues must be subsequently transferred to Matrigel droplets at the correct time according to morphology (**Figs. 2c** and **3c**).

Cerebral tissues will generally expand quickly once placed in Matrigel (**Figs. 2e** and **3f**), and by days 15–20 the entire organoid will be difficult to examine using a standard tissue culture microscope as the tissues are too large at this point. Instead, observe the tissues using a dissecting microscope or stereomicroscope to visualize gross morphology. Fluid-filled cavities can often be seen (**Fig. 2g**), although when located within the tissue mass these are difficult to identify. In addition, retinal regions can be recognized by the presence of pigmented regions reflecting retinal pigmented epithelial identity⁴.

The large size of organoids after Matrigel embedding necessitates analysis by sectioning and immunohistochemical staining (**Box 1**). Cryosections performed at an early stage (12–20 d) will reveal expanding neuroepithelium marked by Sox2 or Pax6 expression (**Table 2**), whereas only occasional neurons are visible¹³. These neuroepithelia are located adjacent to ventricle-like cavities that are often fluid-filled or contain cellular debris. Occasionally, there may be other tissues exhibiting fibroblast-like morphologies, on the basis of histological characterization, and these are thought to be a side effect of impure neural induction owing to a lack of exogenous growth factors or morphogens. However, these should be a minor population and should not affect growth and development of neural tissues.

After 1 month, organoids should begin to exhibit neuronal differentiation, marked by Tuj1 or DCX expression (**Table 2**), leading to progressive expansion and thickening of cerebral tissues over the subsequent 1–2 months (**Fig. 4a**). At this stage, a number of different brain regions are visible (**Table 2**), including forebrain marked by Foxg1 staining (**Fig. 4b**) and choroid plexus marked by TTR staining (**Fig. 4c**), exhibiting a highly convoluted structure and cuboidal epithelial morphology, as well as hippocampus marked by Prox1 and Fzd9 staining (**Fig. 4d**). Finally, ventral forebrain stains positive for the marker Nkx2.1 (**Table 2**), whereas retina exhibits retinal layering and pigmented epithelium.

In addition, cortical regions display evidence of typical progenitor zones, displaying a dense ventricular zone (VZ) populated by Sox2⁺ inner radial glia (**Fig. 4e**), whereas outer radial glia, which are also Sox2⁺, reside outside the VZ. Both populations stain positive for phospho-vimentin during mitosis (**Fig. 4e**) but divide in different locations: inner radial glia divide at the apical surface, whereas outer radial glia divide outside the VZ. Neurons that are generated migrate outward to form a pre-plate; the precursor to the cortical plate, marked by Reelin and Tbr1 (**Table 2**), and intermediate progenitors, marked by Tbr2, can be seen in the region adjacent to the VZ.

If allowed to develop further, organoids will progressively produce more neurons, whereas progenitor zones will shrink and eventually disappear by 5–6 months. Tissues thereafter will be composed of primarily fully differentiated neurons, although other populations such as astrocytes and oligodendrocytes have not been examined. The neuron populations present include various layer identities of the cortical plate^{13,39} (**Table 2**), which will exhibit rudimentary separation into deep and surface layer distributions (**Fig. 4f**). However, the neurons will not display a six-layered architecture such as that seen *in vivo*. Organoids can be further maintained for over 1 year. We have maintained organoids for up to 15 months. Importantly, after 6–7 months, organoids begin shrinking in size, owing to the lack of progenitors and probably to a progressive neuronal cell loss.

ACKNOWLEDGMENTS We are grateful to members of the Knoblich laboratory for their technical expertise and feedback, and particularly to M. Renner and A. Peer for their experimental support. We also thank the Stem Cell and BioOptics core facilities of IMBA and the Institute of Molecular Pathology for their technical support. M.A.L. received funding from a European Molecular Biology Organization (EMBO) postdoctoral fellowship, a Helen Hay Whitney postdoctoral fellowship and a Marie Curie International Incoming Fellowship. Work in J.A.K.'s laboratory is supported by the Austrian Academy of Sciences, the Austrian Science Fund (FWF; projects Z153-B09 and I552-B19) and an advanced grant from the European Research Council.

AUTHOR CONTRIBUTIONS J.A.K. and M.A.L. wrote the manuscript, and M.A.L. performed the experiments.
