

The dependence of viral RNA replication on co-opted host factors

Peter D. Nagy and Judit Pogany

Abstract | Positive-sense RNA ((+)RNA) viruses such as hepatitis C virus exploit host cells by subverting host proteins, remodelling subcellular membranes, co-opting and modulating protein and ribonucleoprotein complexes, and altering cellular metabolic pathways during infection. To facilitate RNA replication, (+)RNA viruses interact with numerous host molecules through protein–protein, RNA–protein and protein–lipid interactions. These interactions lead to the formation of viral replication complexes, which produce new viral RNA progeny in host cells. This Review presents the recent progress that has been made in understanding the role of co-opted host proteins and membranes during (+)RNA virus replication, and discusses common themes employed by different viruses.

Peroxisomes

Organelles that are found in virtually all eukaryotic cells and are involved in the catabolism of fatty acids, D-amino acids and polyamines. Peroxisomes are important for energy metabolism.

The success of viruses as pathogens depends on their ability to replicate within host cells. They achieve this by actively reprogramming host cell metabolism to support the infection process and to allow viruses to escape or suppress host defence mechanisms. As a result, virus-infected cells undergo a series of major changes during infection.

Positive-sense RNA ((+)RNA) viruses include the human pathogens hepatitis C virus (HCV), West Nile virus (WNV), dengue virus (DENV) and severe acute respiratory syndrome coronavirus (SARS CoV). Although (+)RNA viruses have limited coding potential, containing between three and ten genes, these viruses can replicate efficiently in infected host cells owing to their use of host proteins, membranes, lipids and metabolites. Using molecular mimicry, a virus can trick host factors into performing novel functions that frequently target host cells. However, (+)RNA viruses can also induce strong antiviral responses. Viral infection, then, often represents a race between the virus and the host to gain control over the resources of the infected cell.

Following viral entry, the viral (+)RNAs are released and then translated to produce viral replication proteins. These proteins recruit the viral (+)RNA for replication, which requires the assembly of viral replication complexes (VRCs) on subcellular membrane surfaces. Each VRC first produces a complementary negative-sense RNA ((–)RNA) using the original (+)RNA as a template. The (–)RNA is then used by the viral replicase to synthesize new (+)RNA molecules that undergo additional rounds of translation and replication to form new viral particles

that can egress from cells, or move from cell to cell in the case of plant (+)RNA viruses^{1–4} (FIG. 1).

The replication of (+)RNA viruses involves numerous interactions between components from the virus (RNA and proteins) and the host (proteins, membranes and lipids). All characterized (+)RNA viruses assemble VRCs, which contain both viral and host proteins, on intracellular membranes^{1,5–10}. These membranes can be derived from various organelles, such as the endoplasmic reticulum (ER), mitochondria, vacuole, Golgi, chloroplasts and peroxisomes, or from plasma membranes, or they emerge through the formation of novel cytoplasmic vesicular compartments derived from the ER or, possibly, autophagosomal membranes^{11–20}. Thus, subverted host factors have crucial roles in all steps of (+)RNA virus replication. It follows, therefore, that host factors are key determinants of viral pathology as well as viral evolution^{4,9,14,21}.

This Review outlines our current understanding of the host factors that facilitate the replication of (+)RNA viruses. Recent progress has come from *in vitro* replicase assays, reverse genetics approaches, intracellular localization studies, genome-wide screens to identify host factors affecting viral replication, and the use of natural or model hosts. The replication of RNA viruses has been described in several recent publications^{2–4,14,20,22}. Here, an in-depth description of co-opted host factors is provided for representative (+)RNA viruses, including flaviviruses, coronaviruses, picornaviruses, plant tombusviruses and plant bromoviruses. A better understanding of the functions of the co-opted host factors could lead to the development of more potent antiviral strategies.

Figure 1 | Schematic infection cycle of positive-sense RNA viruses. Positive-sense RNA ((+)RNA) viruses enter animal cells by endocytosis and plant cells through wounds. When the virus is inside the cell, the (+)RNA genome is released into the cytosol, where it is translated by the host ribosomes. The resulting viral replication proteins then recruit the (+)RNA to subcellular membrane compartments, where functional viral replication complexes (VRCs) are assembled. A small amount of negative-sense RNA ((-)RNA) is synthesized and serves as a template for the synthesis of a large number of (+)RNA progeny. The new (+)RNAs are released from the VRCs, whereas the (-)RNA is retained. The released (+)RNAs start a new cycle of translation and replication, become encapsidated, and then exit the cells (in the case of animal viruses) or move to neighbouring cells through plasmodesmata (in the case of plant viruses).

Genome-wide approaches

Studies based on high-throughput screens that include a systematic analysis of all or most of the genes encoded by the genome of a particular host organism.

RNA interference

(RNAi). A pathway that, in most eukaryotes, controls which genes are active and their relative activities. The pathway is induced by small interfering RNAs (siRNAs), which are small double-stranded RNAs. Using a library of siRNAs, the expression of each gene in a given cell line or organism can artificially be knocked down.

The discovery of co-opted host factors

As there can be ~20,000–30,000 different proteins in a typical eukaryotic cell, identifying all the proteins that are subverted by a given (+)RNA virus is a daunting task. Numerous approaches have been developed in recent years, and in this section we briefly describe some successful strategies.

Genome-wide approaches have emerged as a powerful means to identify the host factors involved in (+)RNA virus replication. For example, genome-wide screens of *Saccharomyces cerevisiae* (BOX 1) led to the identification of ~130 *S. cerevisiae* genes that affect the replication of tomato bushy stunt virus (TBSV)^{23,24}, ~30 genes that affect TBSV RNA recombination^{25–27}, and ~100 genes that influence the replication of brome mosaic virus (BMV)²⁸. Interestingly, only a small subset of *S. cerevisiae* genes affects replication of both BMV and TBSV, suggesting

that these distantly related (+)RNA viruses depend on mostly different host factors and cellular processes^{23,24,28}.

Genome-wide approaches based on RNA interference (RNAi) have been carried out with *Drosophila C* virus^{16,29}, WNV³⁰, DENV³¹ and HCV^{32–37} in various animal cell types. This approach led to the identification of several hundred host genes that affect (+)RNA virus replication, but this is probably an underestimation owing to the considerable level of genetic redundancy in animals, the variable efficiency of the protein knockdowns, the diversity of experimental conditions and cell types used, and the possible ‘off-target’ effects of some small interfering RNAs (that is, unwanted silencing of non-target genes). Further analysis of the functions of the identified genes will be necessary to confirm that they are indeed co-opted for viral replication.

Global proteomic approaches have also been widely used to identify host components that are part of VRCs or interact with viral replication proteins. For example, yeast two-hybrid screens using proteins from HCV and its human host³⁸ revealed that viral non-structural protein 3 (NS3) and NS5A, which are involved in HCV RNA replication, had the largest number of interacting proteins (214 and 96, respectively). These data indicate that NS3 and NS5A might have crucial roles in reprogramming host cell metabolism during HCV infection through altering the cellular functions of the interacting host proteins. Proteomic approaches have also been used to identify host proteins that interact directly with the viral RNA of coronaviruses, alphaviruses and WNV (viral RNA was purified, and bound host proteins were then identified by mass spectrometry^{9,39–44}) and with the viral RNA of TBSV and BMV (using a protein microarray)^{45,46}.

Taken together, the results of global screens involving HCV, TBSV, BMV, WNV, DENV and *Drosophila C* virus confirm that (+)RNA viruses depend on numerous host cell components for robust RNA replication. Moreover, the overlap among the sets of host proteins identified by different screens for the same virus is low, which suggests that the screens have not yet reached saturation levels; one alternative explanation, however, is that some interactions identified in these screens are fortuitous, nonspecific or non-functional. In any case, these studies clearly indicate that multiple approaches are needed to catalogue the host–virus ‘interactome’ (that is, all the host proteins that specifically interact with viral RNAs and proteins).

The host factors that have been identified through such approaches are likely to have diverse roles during (+)RNA virus replication, including roles as mediators of the intracellular transport of viral proteins and viral RNA; as chaperones that facilitate folding of viral proteins; as helicases or RNA chaperones that assist the folding of viral RNA; as regulators of the switch from translation to replication (by promoting template recognition); and as enzymes involved in lipid metabolism to drive membrane proliferation^{14,24,28,38,47,48}. Notable surprises from the genome-wide screens include the alteration of host lipid metabolism by DENV hijacking of autophagosomes⁴⁹, the requirement for a host microRNA in HCV replication⁵⁰, the involvement of

Box 1 | *Saccharomyces cerevisiae* as a model host

The use of *Saccharomyces cerevisiae* as a model organism to study host–virus interactions has several advantages. Plants and most animals have large genomes with extensive genetic redundancy (functional duplications) in various functions, whereas *S. cerevisiae* has a small genome with only ~6,000 genes, more than 60% of which have been characterized to some extent. The small genome size also means that there is a reduced level of redundancy. In addition, less than 7% of the genes carry introns, which greatly simplifies prediction of the encoded proteins. Moreover, toolboxes and gene libraries are available for the controlled expression of selected genes. One advantage to performing genome-wide screens in *S. cerevisiae* is the availability of collections of knockout mutants, such as the yeast single-gene-knockout (YKO) library, or libraries containing gene sets with regulated expression, such as the yTHC library¹³⁵. Gene libraries with fluorescent tags or affinity tags for identification of the subcellular localization of proteins and for protein purification, respectively, are also available¹³⁶. Microarray chips with DNA oligonucleotides for most *S. cerevisiae* genes, and protein arrays with 4,100 purified proteins from this organism, have been produced¹³⁷. Finally, the databanks for *S. cerevisiae* genes are the most complete among those for eukaryotes. For example, a global analysis of protein localization has been carried out, and detailed protein–protein interaction networks and genetic interaction maps have been constructed^{138,139}.

Proteomic approaches

Global approaches that involve all or most of the proteins encoded by the genome of the particular host.

Yeast two-hybrid screens

Screens looking for protein–protein or protein–nucleic acid interactions in *Saccharomyces cerevisiae* cells. The target protein is screened for physical interaction against a library of full-length or truncated genes that are expressed from a plasmid.

Protein microarray

A microarray based on purified (host) proteins fixed to the chip surface. These arrays are used to identify protein–protein or protein–nucleic acid interactions, substrates of proteins or targets of biologically active small molecules.

Cap-independent translation

A method of translation used by several positive-sense RNA viruses, in which the usual requirement for the interaction of host translation initiation factors with the 5′-cap (a special tag bound to the 5′ end of an mRNA molecule) is circumvented, and select host initiation factors are recruited by alternative means to participate in translation.

SNARE-like protein

One of a large superfamily of proteins with a primary role in vesicle fusion.

membrane-bending host proteins in TBSV and BMV replication^{51,52}, and the effect of a Ca^{2+} , Mn^{2+} -ATPase pump on TBSV RNA replication and recombination⁵³. Interestingly, many of the identified host factors are conserved in eukaryotes, suggesting that (+)RNA viruses selectively target conserved host functions as opposed to host species-specific factors. Such a strategy would help viruses broaden their host range.

Roles of host factors in (+)RNA virus replication

One emerging theme from the genome-wide screens is that many of the host genes that are apparently subverted for (+)RNA virus replication are unique for a given virus. This suggests that (+)RNA viruses have evolved different ways to utilize host cell resources. However, in spite of the diverse sets of host factors that are co-opted by different viruses, functional and mechanistic studies suggest that different host proteins could provide similar functions during replication of viral RNA. The common functions performed by diverse host proteins during various steps of viral replication are discussed below.

Selection and recruitment of viral (+)RNA for replication. The viral (+)RNA participates in several competing processes that are required for successful infection and are also highly regulated and compartmentalized to escape RNA degradation²² (FIG. 1). Therefore, for replication to take place, the viral genomic RNA, together with viral and host factors, must be actively recruited to the appropriate subcellular membrane surfaces.

Viral replication proteins can bind selectively to viral (+)RNA, which probably leads to recruitment of the viral RNA from translation to replication^{54–59}. However, host proteins are also involved. For example, in the case of human poliovirus (PV), a central role for host poly(rC)-binding protein 2 (PCBP2) in RNA template recruitment has been suggested (FIG. 2). PCBP2 is an RNA-binding protein involved in mRNA stabilization and the regulation of transcription and translation, and it binds to the

internal ribosome entry site (IRES) in PV (+)RNA to promote cap-independent translation. When bound to the viral RNA, PCBP2 is cleaved by the PV-encoded RNA-dependent RNA polymerase (RdRp) precursor (3CD) or protease (3C) proteins and, as a result, loses one of its three RNA-binding sites. However, the cleaved form of PCBP2 retains two RNA-binding sites that allows the protein to bind to the cloverleaf structure at the 5′ untranslated region (UTR) of PV (+)RNA (FIG. 2a). This is crucial for PV RNA replication, as it brings together the 3′ and 5′ ends of the viral RNA through interaction with another host protein family, the poly(A)-binding proteins (PABPs)^{60,61} (FIG. 2a). The PV-encoded 3CD is also involved in RNA template selection and in switching of the viral RNA from translation to replication by binding to the cloverleaf-like structure at the 5′ UTR and influencing genome circularization^{54,55,60,62,63}.

Additional host proteins with documented roles in the recruitment of viral (+)RNA from translation to replication are listed in TABLE 1. Overall, these proteins facilitate the recruitment of different viral (+)RNAs for replication (FIG. 1) by protecting the viral (+)RNA from degradation, preventing a collision between the ribosome and the VRC (which compete for the same viral (+)RNA while progressing in opposite directions) and facilitating the selection of a cognate viral (+)RNA for replication (as VRCs of a given virus do not usually support the replication of RNAs from other viruses or from the host).

Targeting viral replication proteins to the replication site. Host proteins participate in targeting the virally encoded replication proteins to their replication sites within the appropriate subcellular compartments. For example, replication of tomato mosaic virus (ToMV) depends on two *Arabidopsis thaliana* membrane proteins termed TOM1 and TOM3, which interact with the helicase-like ToMV replication protein, 130K^{64,65}. TOM1 and TOM3 are also part of the ToMV VRC, in which they probably act as membrane anchors for the replication proteins^{64,65}. Similarly, the human vesicle-associated membrane protein-associated protein A (VAPA), a SNARE-like protein, might serve as a membrane anchor for HCV replication proteins. Indeed, VAPA interacts with the HCV replication proteins NS5A and NS5B⁶⁶, an interaction that could be important for the association of NS5A and NS5B with the intracellular ER-derived membranes that constitute the site of HCV replication. Inhibiting the expression of VAPA, which is partially associated with lipid rafts, results in relocation of NS5B from detergent-resistant to detergent-sensitive membranes⁶⁷. Detergent-resistant lipid rafts — cholesterol- and sphingolipid-rich microdomains — in subcellular membranes could serve as nucleation sites to increase the local concentration of viral replication proteins and facilitate the selective binding of key host factors, ultimately leading to the formation of VRCs^{67,68}. In addition, a geranylgeranylated cellular protein, FBXL2 (F-box and LRR-repeat protein 2; also known as FBL2), might be involved in the recruitment of HCV NS5A to intracellular membranes⁶⁹.

Figure 2 | Remodelling the cellular secretory pathway to support human poliovirus replication. **a** | The human poliovirus (PV) viral replication complex (VRC) assembles on the Golgi-trans-Golgi network (TGN) membrane and contains proteolytically cleaved host poly(rC)-binding protein 2 (PCBP2) and the virally encoded RNA-dependent RNA polymerase (RdRp) precursor protein, 3CD, bound to the 5' cloverleaf-like structure of the positive-sense RNA ((+)RNA), with a host poly(A)-binding protein (PABP) bound to the 3' poly(A) tail. As a result of the interaction between PCBP2 and PABP, the ends of the PV RNA genome are brought into proximity, facilitating the cleavage of 3CD and the release of the RdRp (3D-POL). 3D-POL then starts synthesis of the negative-sense RNA (-)RNA using VPg-UUU (di-uridylylated VPg protein) as a primer. The newly made double-stranded RNA (dsRNA) replicative form (RF), which consists of hybridized (+)RNA and (-)RNA, is partly unwound by the chaperone activity of the host heterogeneous nuclear ribonucleoprotein C (hnRNP C) and the binding of PCBP2 and 3CD to the 5' end of the (+)RNA. After cleavage of 3CD, the released 3D-POL starts (+)RNA synthesis, which will go on for many rounds to produce excess amounts of (+)RNA progeny. **b** | PV begins replicating in the Golgi-TGN compartment. The virally encoded tail-anchored membrane protein 3A binds to the small GTPase ADP-ribosylation factor 1 (ARF1) and promotes the degradation of the host general vesicular transport protein p115, preventing the recruitment of ϵ -COP and β -COP (components of the vesicle coatamer complex 1, which surrounds transport vesicles in the early secretory pathway) to ERGIC. These events slow down vesicular transport from the endoplasmic reticulum (ER) to the Golgi-TGN. The production of additional 3A molecules on the newly made PV (+)RNAs results in remodelling of the Golgi-TGN and ERGIC compartments into viral replication organelles (the VRCs). These organelles provide optimal replication for PV owing to the presence of an increased amount of the lipid phosphatidylinositol 4-phosphate (PtdIns4P), which is produced by the recruited host PtdIns4-kinase- β (PI4KIII β). **c** | Trafficking between the ER and the Golgi in uninfected cells. The ERGIC is decorated with COP1, which is recruited by ARF1 and its guanine nucleotide exchange factor, GBF1.

Geranylgeranylated cellular protein

A protein that has been modified post-translationally by the attachment of one or two 20-carbon lipophilic geranylgeranyl isoprene units (from geranylgeranyl diphosphate) to a cysteine at the carboxy-terminus of the protein. Geranylgeranylation is proposed to function as a membrane anchor for proteins.

Actomyosin

A protein complex composed of actin and myosin.

The transport of potyvirus replication proteins and RNA to the sites of replication occurs in viral protein-induced vesicles that move from the ER to the outer chloroplast membrane. This process seems to rely on the endosomal trafficking pathway and the actomyosin system⁷⁰. It has been proposed that only a single genomic RNA molecule is transported in each vesicle⁷¹. TBSV requires the peroxisomal shuttle protein PEX19, which is necessary for the formation of the peroxisome membrane, and the chaperone heat shock protein 70 (HSP70) to target viral replication proteins to the peroxisome^{72–75}. However, the peroxisomal membrane

is not essential for TBSV replication, as TBSV RNA can replicate in a *pexΔ S. cerevisiae* strain, (which is defective in peroxisome biogenesis) as efficiently as in a wild-type strain^{24,76}. The finding that TBSV can replicate efficiently on the ER membrane in the absence of peroxisomes suggests that some RNA viruses have the flexibility to use different host membranes for their replication. In addition, TBSV replication proteins can be transported to the sites of replication in the form of multimolecular complexes that include viral RNA and some host factors⁷⁷. Pre-organization of replication factors into multicomponent complexes in the cytoplasm

Table 1 | Roles of host factors in replication of positive-sense RNA viruses

Host factors	Viruses	Functions	Refs
RNA-binding proteins			
eEF1 α	TBSV, WNV	RNA recruitment and (–)RNA synthesis	123,125
PCBP2	PV	RNA recruitment and (–)RNA synthesis	60,61
PABP	PV	RNA recruitment and (–)RNA synthesis	62
PTB	HCV, coronaviruses	RNA recruitment and (–)RNA synthesis	141
LSM1	BMV, HCV	RNA recruitment	142,143
hnRNPs	PV, HCV, coronaviruses	RNA recruitment, and (+)RNA and (–)RNA synthesis	129,130, 144,145
TIA1, TIAR	WNV	(+)RNA synthesis	131
GAPDH (Tdh2 and Tdh3)	TBSV	Asymmetric (+)RNA synthesis	133,134
Cellular chaperones			
HSP70	TBSV, FHV	VRC assembly or activation and replication protein recruitment	75,113,117
HSP90	FHV, HCV	VRC assembly or activation	115,120
HSP40	FHV, BMV, flaviviruses	VRC assembly or activation	118,119
CYPA	HCV	Polyprotein processing and RdRp NS5B folding	121
CYPB	HCV	Conformation of the RdRp NS5B	122
FKBP8	HCV	Interaction with NS5A and VRC stabilization	120
Protein targeting			
TOM1 and TOM3	ToMV	Replication protein targeting, and anchoring to membranes	65
VAPA	HCV	NS5A and NS5B binding, and anchoring to membranes	66,67
FBXL2	HCV	NS5A recruitment to membranes	69
PEX19	TBSV	Replication protein recruitment to peroxisome membranes	73
PI4KIII β	PV	Viral RdRp 3D-POL recruitment to membranes	82
Membrane remodelling and lipid synthesis			
ARF1, GBF1	PV	Viral replication organelle formation	82
PI4KIII β	PV	PtdIns4P enrichment in membranes co-opted for VRCs	82
PI4KIII α	HCV	PtdIns4P enrichment in membranes co-opted for VRCs	87
EDEM1, OS9	Coronaviruses	Edemosome formation (possibly containing VRCs)	90
LC3-I	Coronaviruses	VRC formation	90
FASN	DENV	Fatty acid synthesis and VRC formation	91
HLH106	DCV	Fatty acid synthesis and, possibly, VRC formation	16
Ole1	BMV	Fatty acid desaturation and VRC formation	92
Erg25, SMO1, SMO2	TBSV	Sterol synthesis and VRC formation	94
Cellular lipids			
Sterols	TBSV, WNV, HCV	VRC formation	94,99
Fatty acids	DENV, BMV, DCV, HCV	VRC formation	92,101
Phospholipids	TBSV, FHV	VRC formation	104,106
PtdIns4P	HCV, PV	Replication protein binding to membranes, and VRC formation	82,87
Membrane-shaping proteins			
ESCRT proteins	TBSV	VRC formation	52
Reticulons	BMV	VRC formation	51
Other host proteins			
PMR1, ECA1 and ECA3	TBSV	VRC activity and RNA recombination	53

ARF1, ADP-ribosylation factor 1; BMV, brome mosaic virus; CYP, cyclophilin; DCV, *Drosophila* C virus; DENV, dengue virus; ECA, calcium-transporting ATPase, ED type; EDEM1, ER degradation-enhancing α -mannosidase-like 1; eEF1 α , elongation factor 1 α ; ESCRT, endosomal sorting complexes required for transport; FASN, fatty acid synthase; FBXL2, F-box and LRR-repeat protein 2; FHV, Flock House virus; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; HCV, hepatitis C virus; hnRNPs, heterogeneous nuclear ribonucleoproteins; HSP, heat shock protein; LC3-I, non-lipidated microtubule-associated proteins 1A and 1B light chain 3A; NS, non-structural protein; PABP, poly(A)-binding protein; PCBP2, poly(rC)-binding protein 2; PI4K, PtdIns 4-kinase; PTB, polypyrimidine tract-binding protein; PtdIns4P, phosphatidylinositol-4-phosphate; PV, human poliovirus; RdRp, RNA-dependent RNA polymerase; (+)RNA, positive-sense RNA; (–)RNA, negative-sense RNA; TBSV, tomato bushy stunt virus; TIAR, TIA1-related protein; ToMV, tomato mosaic virus; VAPA, vesicle-associated membrane protein-associated protein A; VRC, viral replication complex; WNV, West Nile virus.

could facilitate efficient transport and colocalization of these components to the replication sites and, thus, the assembly of functional VRCs.

Assembly of the VRC

The assembly of a functional VRC occurs on intracellular membrane surfaces and appears to be a highly regulated event. Long-range RNA–RNA interactions, *cis*-acting viral RNA elements and *trans*-acting viral and host factors contribute to the fidelity and efficiency of VRC assembly. The formation of VRCs probably serves to concentrate crucial viral and host factors, facilitate optimal conditions for viral RNA synthesis, and protect sensitive RNA and protein components from recognition and destruction by the host antiviral surveillance system.

Detailed studies of VRCs are challenging, as these complexes form complicated and fragile structures that are frequently part of large viral replication organelles. The HCV VRC contains approximately one viral (–)RNA molecule and five viral (+)RNA molecules, together with hundreds of viral NS proteins, the viral RdRp and subverted host proteins⁷⁸. All these components are present within spherules (invaginations of lipid membranes) that are resistant to proteases and nucleases and are formed from ER-derived membrane. Similar structures have been also observed with alphaviruses, Flock House virus, BMV and TBSV^{11,13,52,79,80}.

Cellular membrane remodelling during VRC assembly. (+)RNA viruses subvert selected organellar membranes by dynamically remodelling and deforming them, giving rise to spherules and vesicles, or by inducing the formation of viral replication organelles^{4,20,52,79–81}. For example, a recent model proposed that PV initially starts replication on pre-existing Golgi and *trans*-Golgi network (TGN) membranes followed, at the peak of PV infection, by redistribution of the newly made viral proteins to viral replication organelles⁸² (FIG. 2b,c). These organelles form close to the ER exit sites and are enriched in various host proteins such as the small RAS-family GTPase ADP-ribosylation factor 1 (ARF1), GBF1 (a guanine nucleotide exchange factor (GEF) for ARF1) and phosphatidylinositol 4-kinase- β (PI4KII β ; also known as PI4K β), which is involved in phosphatidylinositol-4-phosphate (PtdIns4P) synthesis⁸². The subversion of PI4KII β leads to enrichment of the membrane compartment with phosphoinositide lipids such as PtdIns4P⁸² (FIG. 2b). This helps to recruit the PV RdRp, 3D-POL, which binds selectively to PtdIns4P in the membrane. The probable role of GTP-bound ARF1 (the membrane-associated active form) is to recruit other cellular effector proteins to change the membrane curvature, induce the formation of transport vesicles from intracellular organelles and modify the lipid composition of membranes^{83,84}. It is likely that PV proteins 3A and 3CD act synergistically to reorganize the host secretory trafficking pathway in order to facilitate the formation of individual VRCs and replication organelles^{82,83}. Similar replication organelles are probably also formed during flaviviral infections⁸².

HCV uses a similar strategy to build subcellular vesicles or ER-derived ‘membranous webs’, in which HCV VRCs are found⁸⁵. The ER-bound HCV protein NS5A recruits the host kinase PI4KIII α (also known as PI4K α), another protein involved in PtdIns4P synthesis^{37,85,86}. NS5A binding stimulates PI4KIII α kinase activity to enrich the membrane compartment with PtdIns4P⁸⁷. The PtdIns4P-rich membrane can then facilitate the recruitment of additional host factors, such as oxysterol-binding protein 1 (OSBP1), which is required for HCV replication⁸⁸. Both PI4KIII α kinase and PtdIns4P are crucial for the formation and integrity of the membranous web structure of the HCV replication organelle⁸⁷ (FIG. 3a). Remarkably, both PV and HCV seem to use PtdIns4P enrichment to create a favourable microenvironment for RNA replication, but they co-opt different cellular kinases to do so. One possible explanation for this is the availability of these host kinases in different subcellular compartments. For example, ER-bound NS5A co-opts PI4KIII α kinase, which is also ER localized and thus likely to be readily available. By contrast, PV co-opts the Golgi-localized PI4KIII β , which could be available in the ERGIC compartment (FIG. 2). The mechanisms used by HCV and PV for PtdIns4P enrichment of cellular membranes provide a good illustration of a common theme in the biology of (+)RNA viruses: different host proteins can be co-opted by different viruses to provide mechanistically similar functions during viral replication.

In addition, coronaviruses induce the formation of interconnected double-membraned vesicles (DMVs)⁸⁹ by exploiting a regulatory pathway that controls ER-associated protein degradation (ERAD)⁹⁰. Mouse hepatitis virus (MHV), a coronavirus, seems to prevent degradation of the short-lived ER chaperones ER degradation-enhancing α -mannosidase-like 1 (EDEM1) and OS9, which are crucial regulators of ERAD, by trapping them in structures called edemosomes (FIG. 4). It has been hypothesized that the accumulation of MHV replication proteins in edemosomes, which are decorated with LC3-I (non-lipidated microtubule-associated proteins 1A and 1B light chain 3A; a homologue of yeast Atg8, a ubiquitin-like protein that is required for the formation of autophagosomal membranes), transforms these structures into permanent DMVs⁹⁰. The coronaviral replication proteins nsp2 and nsp3 are colocalized with LC3-I on the surface of DMVs during the entire course of MHV infection. Indeed, depletion of LC3 (which results in a reduction of both the lipidated form, LC3-II, and the non-lipidated form) by RNAi severely inhibits DMV formation and MHV replication⁹⁰. The actual function of DMVs has not been fully defined, but they could be the sites of viral replication and virion assembly. The viral content could be released from DMVs by fusion with other membranes or by disintegration of the DMV membranes.

The role of lipids in VRC assembly. Another major group of host factors that affects VRC assembly is involved in regulating the lipid composition of selected intracellular membranes. Membrane lipids can serve as

Viral replication organelles
Large cellular structures that contain many individual viral replication complexes.

Trans-Golgi network
A complex network of membranes and associated vesicles in the so-called *trans*-face of the Golgi, which is involved in sorting and shipping proteins to their intended destinations in the cell.

ER exit sites
Selected areas within the endoplasmic reticulum (ER) from which transport vesicles carrying newly synthesized proteins and lipids bud off for transport to the Golgi apparatus.

ERGIC
(Endoplasmic reticulum–Golgi intermediate compartment). An organelle in eukaryotic cells that mediates trafficking between the ER and the Golgi, facilitating the sorting of cargo.

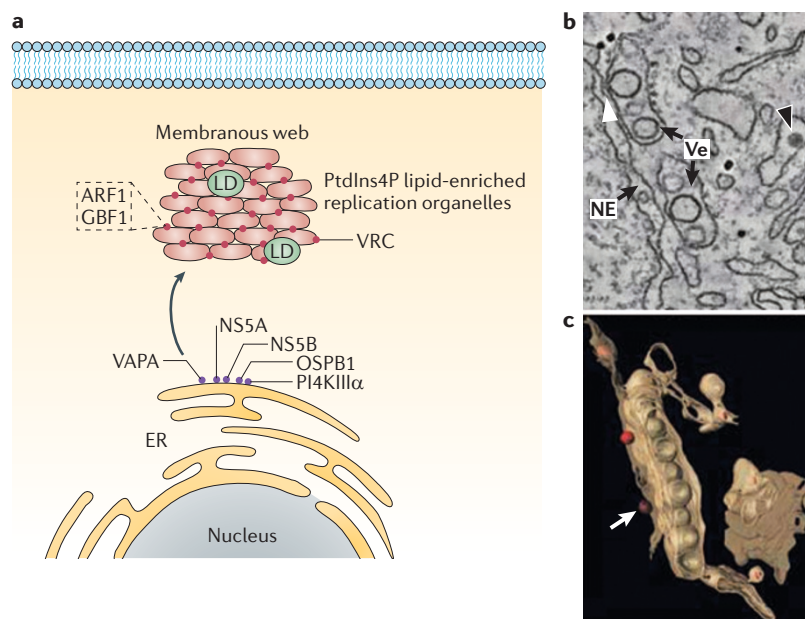

Figure 3 | Structures of the flavivirus replication complexes. **a** | Hepatitis C virus (HCV) replication takes place at a unique subcellular compartment, the endoplasmic reticulum (ER)-derived membranous web, which consists of clusters of HCV-induced vesicles and lipid droplets (LD) and is the proposed site of viral assembly. The virus-encoded replication protein non-structural protein 5A (NS5A) binds to human vesicle-associated membrane protein-associated protein A (VAPA), which, together with NS4B, seems to be important for the association of NS5A and NS5B with cholesterol-rich lipid rafts in the ER-derived membranes. The membrane-bound NS5A then recruits and activates the host kinase phosphatidylinositol 4-kinase- α (PI4KIII α), which leads to an enrichment of phosphatidylinositol-4-phosphate (PtdIns4P) that could facilitate recruitment of oxysterol-binding protein 1 (OSBP1) and the formation of the sterol-rich 'membranous web' to support HCV replication. The high concentration of PtdIns4P probably also facilitates the recruitment of additional host factors to the membranous web. The viral protein NS4B is also important for the formation of the membranous web, possibly by inducing membrane curvature (not shown). **b** | Electron micrograph of the viral replication complexes (VRCs) induced during dengue virus (DENV) infections. The white arrowhead indicates a DENV-induced vesicle in the ER with an opening towards the nuclear envelope; the black arrowhead points to a virus particle in a cisterna close to a Golgi stack. **c** | Three-dimensional modelling of the VRCs induced during DENV infections. The arrow indicates a putative virus budding site, and red spheres represent virus particles. ARF1, ADP-ribosylation factor 1; NE, nuclear envelope; Ve, vesicle. Parts **b,c** are reproduced, with permission, from REF. 140 © (2009) Elsevier.

scaffolds for the assembly of VRCs or can provide crucial lipid cofactors to regulate the function of the viral replicase. For example, the DENV protein NS3 recruits fatty acid synthase (FASN), a major rate-limiting enzyme in fatty acid biosynthesis, to the ER membrane, where DENV replicates⁹¹ (FIG. 3b,c). Moreover, the interaction between NS3 and FASN results in increased FASN activity⁹¹. This leads to *de novo* synthesis of fatty acids that then integrate into the ER and DENV VRC membranes, suggesting that the local synthesis of fatty acids facilitates the expansion of the ER and the formation of DENV VRCs in infected cells. DENV also increases the amount of free fatty acids derived from lipid droplets in mammalian cells by inducing autophagy⁴⁹. The released free fatty acids become available for the assembly of DENV VRCs and lead to an increase in cellular ATP, as they are metabolized by β -oxidation in the mitochondria. Increased ATP is expected to enhance cellular processes

Autophagy

A tightly regulated catabolic process involving the degradation of cellular components through the lysosomal machinery.

and stimulate DENV replication⁴⁹. Thus, DENV and the closely related HCV seem to rely on the local enrichment of different lipids (fatty acids versus PtdIns4P) to promote the assembly of VRCs. These differences could be explained by the different cell types or hosts infected by these viruses (HCV infects liver cells in humans, whereas DENV not only infects humans and non-human primates but also persists in the mosquito vector), which could dictate the available lipid synthesis pathways.

The generation of new membrane surfaces via fatty acid biosynthesis also has a major effect on *Drosophila* C virus replication in *Drosophila melanogaster* cells: depletion of host HLH106, a protein that regulates fatty acid metabolism, blocks the formation of *Drosophila* C virus-induced vesicular compartments¹⁶. In addition, in *S. cerevisiae* inactivation of the gene encoding Ole1, a fatty acid Δ^9 -desaturase that participates in the synthesis of unsaturated fatty acids, reduces the activity of the BMV replicase, probably owing to reduced binding of one of the replicase components (BMV replication protein 1a) to membranes with a lower ratio of unsaturated fatty acids⁹². This results in reduced efficiency of VRC assembly and a low level of replication.

Lipids also seem to affect tombusvirus replication. Electron microscopy images of plant cells infected with tombusviruses show extensive remodelling of membranes and indicate that active lipid biosynthesis occurs^{52,80,93}. Moreover, genome-wide screens in *S. cerevisiae* identified 14 host genes involved in lipid metabolism that affect tombusvirus replication and recombination^{23–25,27}. Detailed studies with Erg25, an important enzyme in the sterol biosynthesis pathway in *S. cerevisiae*, revealed that sterols are crucial for TBSV replication⁹⁴. Sterols are ubiquitous and essential membrane components in all eukaryotes, affecting membrane rigidity, fluidity and permeability by interacting with other membrane lipids and proteins^{95,96}. Sterols are also important for the replication of other (+)RNA viruses, such as HCV, WNV, DENV and Norwalk virus^{97–101}. For example, infection of mammalian cells with WNV leads to redistribution of cholesterol from the plasma membrane to the sites of viral replication and also results in reduced antiviral responses⁹⁹.

Phospholipids are major components of cellular membranes, affecting the size, shape and rigidity of cells and intracellular organelles¹⁰², and they affect the replication of several (+)RNA viruses by their effects on the binding of viral replication proteins to membranes^{103–105}. For example, reducing phospholipid levels in *S. cerevisiae* cells affects TBSV replication in various ways, leading to reduced template activity of the viral replicase, and to altered subcellular localization and reduced stability of the viral replication proteins^{24,106}. Interestingly, genes involved in the production of phosphatidylcholine in *D. melanogaster* are crucial for Flock House virus replication¹⁰⁷. Therefore, the amount and ratio of various phospholipids are important for the replication of several (+)RNA viruses.

Membrane-shaping proteins. Other host factors recruited by some (+)RNA viruses for their own replication are involved in bending membranes. Indeed, dynamic

Figure 4 | Proposed remodelling of the endoplasmic reticulum-associated protein degradation tuning pathway during coronavirus replication. **a** | In normal, uninfected cells, the endoplasmic reticulum-associated protein degradation (ERAD) tuning pathway downregulates the levels of the ER chaperones EDEM1 (ER degradation-enhancing α -mannosidase-like 1) and OS9 in the ER via transport to the lysosome, mediated by LC3-I (non-lipidated microtubule-associated proteins 1A and 1B light chain 3A)-coated edemosomes. **b** | Coronavirus (CoV) infection transforms the edemosomes into double-membraned vesicles (DMVs) that probably contain viral replication complexes (VRCs). The actual orientation of the CoV VRCs in DMVs is not yet known. **c** | Electron tomography-based model of CoV DMVs. Narrow connections between several DMVs form a network that is also connected to the ER. Part **c** is reproduced from REF. 9.

remodelling and deforming of membranes to give rise to unique spherule structures seem to require host proteins. For example, tombusviruses recruit ESCRT (endosomal sorting complexes required for transport) proteins²⁴, which have a major role in sorting cargo proteins from the endosomes to multivesicular bodies by membrane invagination and vesicle formation^{108–111}. Recruitment of ESCRT proteins for TBSV replication might facilitate VRC assembly, including the formation of TBSV-induced spherules (FIG. 5) and vesicles in infected plant cells⁵². Accordingly, the ubiquitylated TBSV p33 was found to interact with *S. cerevisiae* vacuolar protein sorting-associated protein 23 (Vps23; an ESCRT-I protein) and Bro1 (an accessory ESCRT factor)^{52,112}, resulting in the recruitment of Vps23 and possibly Bro1 to peroxisomes, the sites of TBSV replication. This is followed by the recruitment of ESCRT-III proteins (Snf7 and Vps24), which could assist optimal assembly of the VRC, facilitate colocalization of the viral replication proteins p33 and p92 within selected areas in the membrane, and promote the formation of viral spherules by deforming the membranes or stabilizing the ‘neck’ structure (the narrow opening in the spherules that faces the cytosol) (FIG. 5). It seems that protection of the viral RNA is compromised if the VRC assembles in the absence of ESCRT proteins⁵². Thus, ESCRT proteins appear to affect the quality of VRC assembly by contributing to the protection of viral RNA from ribonucleases.

Another group of membrane-shaping proteins, the reticulon homology proteins (Rhps), are involved in assembly of the spherule-like structures during BMV replication in *S. cerevisiae*⁵¹. The BMV helicase-like replication protein 1a recruits Rhps to the perinuclear ER, resulting in spherule formation. In addition, Rhps

affect some functions of protein 1a, such as induction of VRC formation or recruitment of viral RNA. Thus, membrane-shaping proteins of the ESCRT and Rhp groups appear to be involved in the formation of spherules, in which (+)RNA replication can be protected from host immune surveillance.

Roles of host chaperones. Cellular chaperones are also involved in VRC assembly. For example, the tombusvirus replicase was completely inactive when assembled *in vitro* using an *S. cerevisiae* cell-free extract that lacked heat shock protein 70 (Hsp70)¹¹³. The addition of purified recombinant Hsp70 to cell-free extracts was necessary for VRC assembly and replication of the viral RNA¹¹³. Therefore, it seems that Hsp70 is necessary for TBSV replication (FIG. 5). In addition, Hsp70 seems to be important for the insertion of tombusvirus replication proteins into intracellular membranes⁷⁵ and for the folding and stability of the tombusvirus VRC¹¹⁴. Inhibition of the activity or expression of Hsp70 also affects the replication of ToMV and turnip crinkle virus, suggesting that subversion of Hsp70 is common among (+)RNA viruses⁷⁵.

Another example of the role of cellular chaperones is found in the replication of Flock House virus, which is affected by HSP70 and HSP90 proteins as well as by J-domain HSP40-family chaperones^{115–117}. Moreover, Ydj1, a J-domain protein of the HSP40 chaperone family, was proposed to affect the assembly and/or activation of the BMV VRC before (–)RNA synthesis in *S. cerevisiae*¹¹⁸. Also, the assembly or activity of flaviviral VRCs is affected by DNAJC14, an HSP40 family chaperone in mammalian cells¹¹⁹. Thus, various host chaperones are involved in activation and assembly of several (+)RNA virus VRCs, making these chaperones potential targets for antiviral approaches.

Figure 5 | Functions of host factors during tombusvirus replication in *Saccharomyces cerevisiae*. Tombusvirus (such as tomato bushy stunt virus (TBSV)) RNA translation and replication, and the host proteins that affect these processes in a *Saccharomyces cerevisiae* model host. The TBSV RNA-dependent RNA polymerase (RdRp) precursor p92 is activated during the assembly process (as indicated by the colour change) in an as-yet-unknown way. TBSV p33 is an RNA chaperone involved in viral RNA recruitment and assembly of the viral replication complexes (VRCs). The presence of host proteins (denoted host factor (HF) here) is currently hypothetical, and they could be ESCRT-III (endosomal sorting complexes required for transport III) factors. The known cellular functions for the shown host proteins are: elongation factor 1 α (eEF1 α), required for translation elongation; Pex19, a cytosolic shuttle protein involved in transporting peroxisomal membrane proteins to the peroxisome; heat shock protein 70 (Hsp70), a molecular chaperone involved in protein folding, mostly in the cytosol; Erg25, an enzyme for sterol biosynthesis; Cpr1 (also called cyclophilin), a cytosolic prolyl isomerase; ESCRT, a large family of proteins involved in membrane bending, protein transport and degradation via the endosomal pathway; glyceraldehyde-3-phosphate dehydrogenase (GAPDH) enzymes, a ubiquitous protein family that is a key component of cytosolic energy production; Ded1, a DEAD box helicase involved in translation initiation.

In addition, prolyl isomerases (PPIases) are involved in the assembly of the HCV VRCs. The immunophilin FKBP8 (a PPIase) interacts with the HCV phosphoprotein NS5A and with HSP90, and this interaction may have a role in stabilizing the VRC¹²⁰. Even more importantly, the cytosolic protein cyclophilin A (CYPA; also known as PPIase A), which has PPIase activity, is crucial for assembly of the HCV VRC, probably because it affects processing of the HCV polyprotein and folding of the RdRp NS5B¹²¹. CYPB (also known as PPIase B), another cellular PPIase, also affects the conformation of NS5B, which in turn affects the RNA-binding ability and template activity of this viral protein¹²².

Synthesis of progeny viral RNA

Another common theme in the replication of (+)RNA viruses is the subversion of various host RBPs to facilitate viral RNA synthesis. Several of the RBPs that are co-opted by different viruses probably have mechanistically similar functions during viral replication, as discussed below.

Host factors that regulate (–)RNA synthesis. Although all (+)RNA viruses encode their own RdRps and usually 1–6 auxiliary replication proteins, host proteins are predicted to participate in each step of RNA synthesis. For example, elongation factor 1 α (eEF1 α), which is a highly abundant cellular protein that delivers the aminoacyl-tRNA to the elongating ribosome, is a permanent resident of the tombusvirus VRC and binds to the 3' UTR of the TBSV RNA (in yeast, this is the TEF1 and TEF2 forms of eEF1 α , but in plants and mammals the specific form of eEF1 α involved is not yet known)⁴⁶. Mutational analysis of eEF1 α , in combination with *in vitro* replication studies, suggests that eEF1 α promotes (–)RNA synthesis by the tombusvirus VRC by binding to both the RdRp and the 3' UTR of the (+)RNA molecule, thus facilitating the proper positioning of the RdRp on the template RNA for efficient initiation of RNA synthesis¹²³. Similarly, eEF1 α binds to the 3' UTR of the (+)RNA of WNV, and certain mutations introduced at the eEF1 α -binding sites of the viral RNA inhibit both (+)RNA–eEF1 α binding and (–)RNA synthesis^{21,124}. Moreover, eEF1 α colocalizes with the WNV VRC in infected cells, indicating that eEF1 α facilitates the interaction between the viral replicase and the WNV RNA 3' UTR¹²⁵. The involvement of eEF1 α in viral (+)RNA replication might be common, as eEF1 α binds to many viral (+)RNAs and replication proteins, and its high abundance in cells might facilitate its recruitment for viral replication. Indeed, the bacterial homologue of eEF1 α , termed EF-Tu, is known to affect (–)RNA synthesis for the bacteriophage Q β ^{126,127}, suggesting that subversion of eEF1 α -like host proteins by (+)RNA viruses might be an ancient process.

Other host RBPs seem to facilitate proper positioning of the viral RdRp on the RNA template to promote (–)RNA synthesis. For example, co-opted PCBP2 forms a complex with PV 3CD while bound to the cloverleaf structure in the PV (+)RNA 5' UTR¹²⁸ (FIG. 2a). After activation of PV RdRp by cleavage of 3CD, the replication

initiation complex at the 5' end is brought to the 3' end by genome circularization through the interaction of PCBP2 with the PABP bound to the poly(A) sequence in the 3' UTR⁶² (FIG. 2a). Interactions between polypyrimidine tract-binding protein (PTB; also known as heterogeneous nuclear ribonucleoprotein I), which is bound to the 5' UTR of the MHV genome, and hnRNPA1, which is bound to 3' UTR, might have a comparable role in facilitating (–)RNA synthesis by viral RdRp. Mutations in MHV RNA that impair binding of host factors to the UTRs inhibit replication of the viral RNA¹²⁹.

Host factors that regulate (+)RNA synthesis. Host RBPs are also important for (+)RNA synthesis. For example, hnRNPC, which binds to the 3' end of the PV (–)RNA through its RNA recognition motif (RRM) domain (containing an arginine-rich motif), also interacts with the replication protein 3CD, probably recruiting 3CD to the (–)RNA template¹³⁰. The RNA chaperone activity of hnRNPC could facilitate the folding of (–)RNA or the replicative double-stranded RNA intermediate into a replication-compatible conformation, thus promoting RNA synthesis¹³⁰ (FIG. 2a).

Other host proteins involved in (+)RNA synthesis are the stress granule protein TIA1 and TIA1-related protein (TIAR), which contain three RRM motifs. TIA1 and TIAR have been proposed to bind to WNV (–)RNA, promoting efficient (+)RNA synthesis^{42,131}. In addition, the sequestration of these proteins for WNV replication might inhibit the formation of stress granules and P-bodies, thus potentially blocking mRNA degradation¹³¹.

Regulation of asymmetric RNA synthesis by host factors. During TBSV replication, host glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is involved in regulation of asymmetric RNA synthesis (FIG. 5). This hallmark feature of (+)RNA viruses leads to the generation of 10- to 100-fold more (+)RNA progeny than (–)RNA replication intermediates. GAPDH, which is present in the tombusvirus VRC¹¹⁴, is a highly conserved, abundant and ubiquitous protein that is a key component of cytosolic energy production¹³². Downregulation of GAPDH inhibits TBSV replication in *S. cerevisiae* and in plants and results in production of (+)RNAs and (–)RNAs in a 1:1 ratio, instead of asymmetric RNA synthesis¹³³. GAPDH might promote asymmetric RNA synthesis by selectively anchoring the (–)RNA template to the VRC, allowing efficient access of the (–)RNA replication intermediate to viral RdRp, whereas (+)RNA progeny (which are not bound by GAPDH) are released from VRC into the cytosol¹³³. In addition, GAPDH stimulates (+)RNA synthesis *in vitro* by recruiting the TBSV replication protein p92 to the (–)RNA template within the VRC¹³⁴.

Other host factors that affect RNA synthesis. In addition to the above RBPs, other host factors can affect viral RNA synthesis by regulating VRC activity. For example, Pmr1, an *S. cerevisiae* Ca²⁺,Mn²⁺-ATPase pump, affects the activity of the tombusvirus replicase. Inactivation of

PMR1 increases the rate of TBSV RNA recombination and replication⁵³. It has been proposed that the viral replicase uses the far more abundant Mg²⁺ over Mn²⁺ when Pmr1 works efficiently (that is, at low cytosolic Mn²⁺ concentrations), leading to a normal replication rate and low-frequency RNA recombination⁵³. However, inhibiting Pmr1 increases the level of cytosolic Mn²⁺, promoting more efficient use of Mn²⁺ by the viral replicase, resulting in an increased replication rate and high-frequency RNA recombination. Host Ca²⁺,Mn²⁺-ATPase pumps might also influence other viral RdRps, as Mn²⁺ is known to affect the activity of several DNA and RNA polymerases *in vitro*.

Conclusions and future directions

Several common themes are emerging from studies of the functions of host factors in (+)RNA virus replication. Many of the identified host factors are conserved in eukaryotes, suggesting that these viruses selectively target highly conserved host functions. Moreover, a large fraction of the subverted host proteins is unique for a given virus, indicating that (+)RNA viruses have evolved different ways to exploit host cells. However, although the co-opted host proteins are diverse, they might fulfil similar or related functions during viral RNA replication.

Common host factors that are recruited by (+)RNA viruses for their replication include: RBPs that facilitate viral RNA synthesis; proteins involved in membrane bending that contribute to the formation of membrane-bound replication complexes; lipid synthesis enzymes (such as FASN and PI4KIIIβ) that affect lipid composition and have a role in creating a favourable micro-environment for viral replication; and chaperones and PPIases that facilitate the proper folding and functions of viral replication proteins during VRC assembly.

In spite of these recent advances, our current understanding of (+)RNA virus replication and virus–host interactions is far from complete. Further application of proteomics and genome-wide studies will expand this area of research. Importantly, functional and mechanistic studies based on biochemical approaches (such as the use of cell-free extracts and single-molecule techniques) in combination with live-cell imaging will be needed to test all the candidate proteins identified. *In vitro* reconstitution of VRCs would be extremely useful for the dissection of unknown functions of the host proteins that are co-opted for viral replication. Super-resolution imaging and electron tomography to determine the position and orientation of host proteins within VRCs will advance our understanding of the mechanisms involved in (+)RNA virus replication. In addition, proteomics can be used to study the possible roles of post-translational modifications of viral replication proteins. These advances should lead to a better understanding of viral replication and the interactions between host factors and (+)RNA viruses, which are key aspects of viral pathogenesis. Characterizing the functions of host factors in (+)RNA virus replication might also help develop novel antiviral strategies and potential biotechnological applications of these viruses.

Stress granule

A type of dense protein–RNA aggregation in the cytosol, not surrounded by membrane, that appears when the cell is under stress. Stress granules may store and protect RNAs from harmful conditions under stress, and they serve as decision points for untranslated mRNAs for further storage, degradation or translation re-initiation.

P-bodies

(Processing bodies). Distinct foci within the cytoplasm, consisting of enzymes involved in mRNA turnover.
