Structure of the immature Zika virus at 9 Å resolution

Vidya Mangala Prasad, Andrew S Miller, Thomas Klose, Devika Sirohi, Geeta Buda, Wen Jiang, Richard J Kuhn & Michael G Rossmann

The current Zika virus (ZIKV) epidemic is characterized by severe pathogenicity in both children and adults. Sequence changes in ZIKV since its first isolation are apparent when pre-epidemic strains are compared with those causing the current epidemic. However, the residues that are responsible for ZIKV pathogenicity are largely unknown. Here we report the cryo-electron microscopy (cryo-EM) structure of the immature ZIKV at 9-Å resolution. The cryo-EM map was fitted with the crystal structures of the precursor membrane and envelope glycoproteins and was shown to be similar to the structures of other known immature flaviviruses. However, the immature ZIKV contains a partially ordered capsid protein shell that is less prominent in other immature flaviviruses. Furthermore, six amino acids near the interface between pr domains at the top of the spikes were found to be different between the pre-epidemic and epidemic ZIKV, possibly influencing the composition and structure of the resulting viruses.

The current ZIKV epidemic, which started in Brazil in 2015, has given rise to reports of microcephaly in fetuses¹ and Guillain-Barre syndrome² in adults. ZIKV is a member of the *Flaviviridae* family and, like some other flaviviruses, is transmitted by mosquitos. The flaviviruses include other significant human pathogens such as dengue virus (DENV), West Nile virus (WNV), yellow fever virus and Japanese encephalitis virus³. Flaviviruses are enveloped viruses containing a single-stranded, positive-sense RNA genome of ~11 kb (ref. 3). In virions, the RNA genome complexes with multiple capsid protein molecules, surrounded by a membrane⁴. The extracellular, mature form of the virus has an outer surface that forms an icosahedral shell with 90 dimers of the envelope (E; ~495 amino acids) and membrane (M; ~75 amino acids) proteins, arranged in a herringbone pattern⁵. The E glycoprotein is involved in receptor binding, attachment and virus fusion during cell entry⁴. The M protein is mostly unexposed and has a significant transmembrane component. The cryo-EM structures of various mature flaviviruses^{5–7}, including ZIKV^{8,9}, are known and have a similar overall architecture (Fig. 1a,b). During infection of host cells, virions first assemble into an immature form of the virus in the endoplasmic reticulum³. The immature virus is composed of 60 trimeric spikes of the precursor membrane (prM) and E proteins; the pr domain (~90 amino acids) of the prM protein protects the fusion loop on the E protein from nonproductive interactions within the cell¹⁰. In the low-pH environment of the trans-Golgi network, immature virions undergo proteolytic processing by furin, a cellular protease¹¹, and the pr domain is cleaved from the prM protein during maturation. The virus then releases the pr domain to form the mature virion on exit from cells¹².

Although only the mature form of the virus is considered infectious, because of the varying efficiency of pr cleavage in flaviviruses³, the virus population secreted from host cells is a mixture of mature, partially mature and immature virions. Immature forms of flaviviruses such

as DENV (ref. 13) and WNV (ref. 14) can become infectious through antibody-dependent entry into host cells. ZIKV is no exception to this observation of a mixed population of virus maturation states on release from infected cells. It is therefore probable that the immature form of ZIKV also plays a role in virus infection and spread.

Here we report a cryo-EM structure of the immature ZIKV (H/PF/2013 strain of Asian lineage) at a resolution of 9 Å. This structure has been used to fit the crystal structures of the prM and E proteins into the cryo-EM map and compared with immature virion structures from other flaviviruses.

RESULTS

Cryo-EM structure of immature ZIKV

We infected mosquito C6/36 cells with ZIKV (strain H/PF/2013) for 16 h at 30 °C, and then added NH₄Cl to produce immature virions. The purified immature ZIKV was plunge-frozen on grids and examined using an FEI Titan Krios electron microscope with a Gatan K2 Summit detector. Although the purified viruses were predominantly spiky, as expected for immature particles, they appeared to have some heterogeneity. A total of 9,315 particles were selected and used to generate a cryo-EM map at a resolution of 9.1 Å based on the 0.143 Fourier shell correlation criterion (Supplementary Fig. 1).

The cryo-EM reconstruction of the immature ZIKV has a spiky appearance with a diameter of approximately 600 Å (Fig. 1c,d). Densities for the individual prM–E heterodimers within the spikes are clearly visible in the immature ZIKV cryo-EM map. In addition, the individual transmembrane regions of the E and M proteins are easily recognizable. The crystal structure of the DENV-2 prM–E ectodomain heterodimer (PDB 3C6E)¹⁵ was fitted into the immature ZIKV cryo-EM map at the three independent positions with one trimeric spike (Supplementary Fig. 2a–c and Online Methods). The transmembrane helices of the M and E proteins from the mature ZIKV were also fitted

Figure 1 Cryo-EM structure of immature Zika virus. Surface view (**a,c**) and cross-section (**b,d**) of mature (top)⁸ and immature ZIKV (bottom), colored radially according to the keys. Thick black arrows indicate the densities between the inner RNA core and the viral membrane (double-ended arrow indicates the inside and outside layers of the membrane) in immature ZIKV. The numbered, thin black arrows in **b** and **d** give the icosahedral symmetry axes. The asymmetric unit is shown as a black triangle in **a** and **c**. Scale bar, 100 Å.

individually into the transmembrane densities in the immature ZIKV cryo-EM map (**Supplementary Fig. 2d**). A comparison of these fitted components in ZIKV to the complete trimeric prM-E spike of immature DENV-1 (ref. 16) showed little difference in spatial arrangement.

Glycosylation in immature ZIKV

The fitting procedure showed that Asn69 of the pr domain in ZIKV is glycosylated, as it is in DENV (**Supplementary Fig. 3a**), but the glycosylation at Asn67 in the DENV E protein is not preserved in ZIKV (**Supplementary Fig. 3b**). Additional density was also found associated with each of the three Asn154 residues in immature ZIKV (**Supplementary Fig. 3c**), showing that Asn154 is glycosylated as expected from the protein sequence. Similarly, Asn154 on the E protein was glycosylated in the mature ZIKV and was found to cover the fusion loop in the adjacent E monomer, suggesting that this site may be important for viral entry⁸.

Inner shell of capsid protein in immature ZIKV

We observed residual density between the inner membrane layer and the RNA core (**Fig. 1d**). The density is immediately below the base of each of the spikes and has a volume and shape that matches that of dimeric capsid protein structure^{17,18} (**Figs. 1d** and **2a–d**). This potential capsid density is more evident in immature ZIKV than in immature DENV-1 (ref. 16). Mature flavivirus structures^{5,8} lack density in this region (**Fig. 1b**), suggesting a rearrangement of the capsid shell during maturation. The capsid density is in contact with the inner layer of the viral membrane and is close to the transmembrane domains of the E and M proteins, suggesting interactions that might be essential during virion assembly. The formation of an inner shell of capsid proteins also provides a benefit for recruitment of the viral genome. Moreover, the advantage of having a somewhat unstable inner core, as shown here for ZIKV, could be that it facilitates transfer of the genome into a host cell during infection.

Figure 2 Cross-section of the immature ZIKV contoured to show the inner capsid shell. (**a**) Cross-section of immature ZIKV projected down an icosahedral two-fold axis. The putative location of the inner capsid shell lies between the dashed concentric circles. Scale bar, 100 Å. (**b,c**) Magnified view of the region outlined by the red rectangle in **a**, showing the fitted NMR spectroscopy structure of the DENV-2 capsid protein (PDB 1R6R). Panel **b** is rendered at the same contour level as **a** (2.5), whereas **c** is rendered at a higher contour level (3.5), showing that the capsid protein density height is only about half of that of the outer glycoproteins. (**d**) Magnified view of the region outlined by the green rectangle in **b** showing the fitted DENV-2 capsid protein structure along two orthogonal views. Scale bars in **b–d**, 25 Å.

Interactions between prM-E heterodimers of the trimeric spikes

The three prM-E heterodimers that form a spike in immature flaviviruses are not related by threefold symmetry. Thus the interactions of any one of the three heterodimers with the two others in a spike is different. Our structure shows that the trimeric spike in immature ZIKV is held together at its external tip through interactions between the pr domains and the fusion loop of one of the E proteins (**Fig. 3a,b**). The residues involved in these interactions between prM-E heterodimers within the spikes can be deduced from the DENV-2 prM-E crystal structure fitted into the trimeric spike density of ZIKV, and the sequence alignment of prM-E for DENV-2 and ZIKV (H/PF/2013) (**Fig. 3b**, **Supplementary Fig. 4** and **Supplementary Table 1**). Apart from these interactions at the top of the trimeric spikes, the base of the spike is stabilized by interactions between residues in domain III of the ZIKV E protein in one spike to the domain II of E protein from an adjacent spike (**Fig. 3c**, **Supplementary Fig. 4** and **Supplementary Table 1**).

Compared to the other viral proteins, the prM protein has the lowest percentage identity among flaviviruses (~40%). Even when different strains of ZIKV are being compared, the pr domain has the highest percentage of changes in its amino acid sequence compared to other ZIKV proteins¹⁹. We noted six amino acid changes in the pr domain between pre-epidemic and epidemic ZIKV strains, and all of these were contained in the ~40 amino acids at the start of the pr domain¹⁹ (**Fig. 3**). These amino acid changes clustered near the interface between pr domains and were involved in the interactions within trimeric spikes (**Fig. 3b** and **Supplementary Fig. 4**). A few of these amino acid substitutions involve dramatic changes in the polarity of the residues—for example, Lys21 and His35 in pre-epidemic ZIKV strains are substituted for by Glu21 and Tyr35 in the epidemic strains. Similarly, the change of Val26 to Pro26 between the pre-epidemic and epidemic ZIKV strains

Figure 3 Interface between prM-E heterodimers. **(a)** Ribbon diagram of prM-E heterodimers in a trimeric spike of immature ZIKV. The prM-E heterodimers show E proteins in green, red and blue, whereas the pr domains are in brown, purple and black. Scale bar, 50 Å. **(b)** Diagram of the prM-E arrangement in **a**, using the same color-coding. The three prM-E molecules are marked 1, 2 and 3. The two different interaction regions within trimeric spikes are indicated by the gray dashed boxes. The molecule numbers and residues involved on either side of an interaction surface are shown in boxes colored according to the protein involved. **(c)** Diagrammatic representation of the trimeric spikes across adjacent asymmetric units. The interaction regions between E proteins from different spikes are indicated by gray dashed rectangles. A single trimeric spike is outlined in orange. The asymmetric unit is outlined by a black triangle.

could potentially affect the local C α backbone structure in the pr domain. Thus, these amino acid changes possess the ability to alter the nature of interactions within a trimer spike among the different strains of ZIKV.

DISCUSSION

Comparison between the residues near the interface within trimeric spikes in DENV to those in the epidemic ZIKV strains showed that the interface in DENV is more positively charged than that in ZIKV (Supplementary Fig. 4). The lack of such closely positioned positively charged residues in ZIKV could imply comparatively more stable interactions within spikes in immature ZIKV. This would have an effect on the dynamics of conformational change between the immature and mature virion states, wherein the trimeric spikes have to break contacts to form the dimeric interactions seen in mature virions. Thus, ZIKV might tend to have a higher proportion of partially immature virions in their populations than of completely mature virions. This partial maturation of virions is seen in all flaviviruses, but the degree of heterogeneity of virion particles varies between flaviviruses³. A structurally heterogeneous virion population is advantageous to a viral pathogen, as it limits the uniform availability of neutralizing epitopes on the virion, making it more challenging for the host immune system to inhibit the virus. This phenomenon is observed not only with other flaviviruses, such as WNV^{20,21}, but also for other debilitating viruses such as HIV-1 (refs. 22,23). In addition, non-neutralizing antibody responses can be counteractively used by ZIKV for antibody-dependent entry of host cells^{24,25}. Thus, local differences between ZIKV strains could modulate the sensitivity of ZIKV to antibodies and impact the potency of viral infection.

ONLINE METHODS

Virus preparation and purification. Approximately 1×10^9 C6/36 cells (ATCC CRL-1660) were infected with Zika virus (strain H/PF/2013) at a multiplicity of infection of 4 for 16 h at 30 °C. The inoculum was removed, and cells were rinsed three times with phosphate-buffered saline (pH 8.0) and incubated for 2 h at 30 °C in minimal essential media containing 2% FBS, 25 mM HEPES, pH 7.3, and 30 mM NH_4Cl . The process was repeated two more times for a total of three incubations at 30 °C in cell culture media containing 30 mM NH_4Cl . Media was collected 72 h after infection, and immature virus particles were purified according to previously described methods¹². Briefly, virus particles were precipitated from the media by overnight mixing with 8% polyethylene glycol 8000 at 4 °C. This mixture was then pelleted at 8,900g for 50 min at 4 °C. Resuspended particles were pelleted through a 24% sucrose cushion, resuspended in 0.5 mL of NTE buffer (20 mM Tris, pH 8.0, 120 mM NaCl, 1 mM EDTA) and purified with a discontinuous gradient in 5% intervals from 35% to 10% potassium tartrate, 20 mM Tris, pH 8.0, and 1 mM EDTA. Immature virus was extracted from the gradient and concentrated, and the buffer was exchanged for NTE buffer.

Cryo-electron microscopy data collection. The purified immature ZIKV sample was plunge-frozen on ultrathin lacey carbon EM grids (Electron Microscopy Sciences). The grids were examined using an FEI Titan Krios electron microscope with a Gatan K2 Summit detector. Cryo-EM images were collected at a magnification of 22,500 $\times$ in the 'super-resolution' data collection mode. The pixel size of the collected images was 0.65 Å. The total exposure time for producing one image composed of 38 frames was 7.6 s and required a dose rate of 4.7 electrons Å⁻² s⁻¹. A total of 3,341 images were collected and 14,351 particles were boxed manually using the e2boxer program in EMAN2 (ref. 26).

Three-dimensional reconstruction and data analysis. Nonreference two-dimensional classification was performed using the Relion software package²⁷, resulting in the selection of 9,315 particles. This data set was split into two equal subsets as required by the 'gold standard' for determining the quality of the cryo-EM reconstruction. The JSPR program²⁸ was used for initial model generation and refinement of the orientations of the selected particles. The selected particles were used to generate a cryo-EM map at an average resolution of 9.34 Å based on the 0.143 Fourier shell correlation criterion. After the application of soft spherical masks, the resolution improved to 9.14 Å.

Fitting of crystal structures into the cryo-EM map. The crystal structure of the immature DENV-2 prM-E heterodimer (PDB 3C6E) was used to fit a trimeric spike in the immature ZIKV map. Sequential fitting of the three prM-E molecules into the trimeric spike density was carried out using UCSF Chimera software²⁹. The C α backbone of the transmembrane helices of M and E proteins from the mature ZIKV structure (PDB 5IRE) were also fitted into the transmembrane

regions of the three prM-E heterodimers. The solution structure of DENV-2 capsid protein (PDB 1R6R) was placed into the density between the inner layer of the viral membrane and the RNA core of immature ZIKV, according to a previously suggested orientation of the capsid protein in the virion¹⁷. The ectodomain structure (PDB 5IRE)⁸ of mature ZIKV E protein was split into two parts, with one molecule containing domains I and III and the second molecule containing domain II. These different parts were superposed independently on the immature dengue prM-E molecule to determine the interaction regions between E proteins from adjacent spikes. Interface regions between different protein partners were identified as residues with less than 6 Å distance between their corresponding C α backbones.

Multiple sequence alignment. Sequence alignments of the pr domains and E glycoproteins among flaviviruses were carried out using the MAFFT program³⁰ and rendered using ESPript software³¹. The sequences for comparison were obtained from the ViPR resource database³². The representative flavivirus strains used in the comparison were Zika-Asian (H/PF/2013 strain), Zika-African (1968-Nigeria strain), West Nile virus (NY99 strain), Japanese encephalitis (SA14 strain), yellow fever (Asibi strain) and the four dengue virus serotypes (Western Pacific, S16803, CH53489 and IND1979 strains). In this study, the residue numbers for pr and E used were chosen on the basis of the ZIKV sequence and structure, though the numbers assigned to the residues during multiple sequence alignment may be slightly shifted in **Supplementary Figure 4**.

Data availability. The atomic coordinates of the fitted dengue virus-2 prM-E molecules and mature ZIKV E and M transmembrane components along with the cryo-EM density map of the immature ZIKV are available at the Protein Data Bank and Electron Microscopy Data Bank with accession codes 5U4W and EMD-8508, respectively.
