Background: In the Multiethnic Cohort Study, Japanese Americans (JA) have lower mean body mass index (BMI) compared with Caucasians, but show a higher waist-to-hip ratio at similar BMI values and a greater risk of diabetes and obesity-associated cancers.

Objective: We investigated the abdominal, visceral and hepatic fat distribution in these Asian and Caucasian Americans.

Design: A cross-sectional sample of 60 female cohort participants (30 JA and 30 Caucasians), of ages 60–65 years and BMIs 18.5–40 kg m⁻², underwent anthropometric measurements and a whole-body dual energy X-ray absorptiometry (DXA) scan: a subset of 48 women also had abdominal magnetic resonance imaging (MRI).

Results: By design, JA women had similar BMIs (mean 26.5 kg m⁻²) to Caucasian women (27.1 kg m⁻²). JA women were found to have a significantly smaller hip circumference (96.9 vs 103.6 cm; $P=0.007$) but not a significantly lower DXA total fat mass (25.5 vs 28.8 kg; $P=0.16$). After adjusting for age and DXA total fat mass, JA women had a greater waist-to-hip ratio (0.97 vs 0.89; $P<0.0001$), DXA trunk fat (15.4 vs 13.9 kg; $P=0.0004$) and MRI % abdominal visceral fat (23.9 vs 18.5%; $P=0.01$) and a lower DXA leg fat mass (8.2 vs 10.0 kg; $P<.0001$). Their MRI % subcutaneous fat (33.4 vs 30.2%; $P=0.21$) and % liver fat (5.8 vs 3.8%; $P=0.06$) did not significantly differ from that of Caucasian women.

Conclusions: Our findings build on limited past evidence, suggesting that Asian women carry greater abdominal and visceral fat when compared with Caucasian women with similar overall adiposity. This may contribute to their elevated metabolic risk for obesity-related diseases.

Introduction

Body mass index (BMI: weight (kg)/height (m)²) is the most commonly used measure of overall body fatness. However, body fat deposition in the abdominal region is known to be a better predictor than BMI of the risks of cardiovascular disease,¹ diabetes² and, possibly, obesity-associated cancers.^{3–5} Similarly, specific metabolic phenotypes, such as of insulin resistance, are better predicted by waist size⁶ and by direct measurement of trunk fat using dual energy X-ray absorptio-

metry (DXA) than by BMI.⁷ Studies of more detailed abdominal fat distribution using magnetic resonance imaging (MRI) or computed tomography have associated intraperitoneal visceral adipose tissue (VAT), more than subcutaneous adipose tissue (SAT), with a greater metabolic risk.^{8,9} This is thought to be due to the drainage of free fatty acids from VAT to the portal venous system, which, therefore, promotes hepatic insulin resistance and dyslipidemia more effectively than SAT.^{10–12} Thus, direct measurements of liver fat content may also be informative when investigating the metabolic effects of excess weight. It is estimated that as many as 20–30% of adults in developed countries have obesity-related non-alcoholic fatty liver disease.¹³

Along with age and sex, ethnicity is a major determinant of body fat distribution. Studies to date suggest that, compared with Whites, abdominal and visceral adiposity is

greater among Latinos, and visceral adiposity is lower among African Americans.^{14–16} However, data comparing Asians with Caucasians are limited, although Asians manifest a higher obesity-related disease risk.^{17–19} In a small study, greater VAT in proportion to total adiposity was detected among young women (but not men) of mixed Asian ancestry ($n = 18$), compared with Whites ($n = 36$).²⁰ In another study, greater VAT was observed in Filipinas compared with their Caucasian or African-American counterparts of similar or higher BMI.²¹ Greater visceral adiposity was also reported among the Canadians of Chinese descent, compared with Caucasians.²² There is an even greater paucity of data on ethnic differences in liver fat content.²³ One study compared middle-aged men in Japan and non-Hispanic White men in the US and found a lower mean BMI but higher liver fat content among the Japanese.²⁴

In an ongoing multiethnic cohort of older adults, based in Hawaii and California, we recently observed a higher BMI-adjusted waist-to-hip ratio and higher BMI-associated risks of incident diabetes²⁵ and breast and colorectal cancers (White *et al.*, personal communication, 2010) among Japanese Americans (JA) compared with Whites, even after adjusting for other risk factors. In order to better understand whether these risk differences may stem from different body fat distribution, we conducted detailed anthropometry, DXA and MRI studies in a subset of 60 JA and White, apparently healthy women from the same cohort. Women were chosen for this initial study because they have greater variability in waist size for a given level of BMI compared with men²⁶ and because of their susceptibility to accumulate more abdominal adiposity after menopause.²⁷

Subjects and methods

Recruitment

Participants for the current study were recruited from the ongoing Multiethnic Cohort Study. This prospective study conducted in Hawaii and Los Angeles consists of over 215 000 men and women who were of ages 45–75 years at baseline (1993–1996) and of mainly five racial/ethnic groups, as described previously.²⁸

Women who were 60–65 years of age, as of September 2009, who reported both parents being of either Japanese or White ethnicity on the baseline questionnaire and who responded to the most recent Multiethnic Cohort follow-up questionnaire (completed in 2003–2008) were eligible for the present study. In order to ensure that Japanese and White women would have a similar BMI distribution, stratified sampling was performed. Equal numbers of women were recruited from the following BMI categories within each ethnic/racial group: 18.5–21.9, 22–24.9, 25–26.9, 27–29.9 and 30–35 kg m⁻². The BMI category used for subject selection was determined from self-reported weight and height in the most recently completed third Multiethnic

Cohort questionnaire and confirmed during recruitment. Exclusion criteria also included: current or recent smoking (<2 years); use of medications that may interfere with metabolism and body composition (chemotherapy, insulin or weight-loss drugs); substantial weight change (loss or gain of 20 pounds or more) in the past 6 months; pre- or perimenopausal status (had menses in the past 12 months); BMI outside the target range (18.5–35 kg m⁻²); and report of any soft or metal implants/objects in the body that could bias the body composition estimates or put subjects at risk in the MRI magnetic field (for example, pacemakers, cardiac valves, stents).

Out of the 218 women contacted, 46 (21%) were ineligible because of medication use ($n = 21$), implants or mastectomy ($n = 6$), self-reported BMI <18.5 or >35 kg m⁻² ($n = 7$), smoking ($n = 5$), possible claustrophobia ($n = 4$) and difficulty donating blood ($n = 3$). In addition, some women were either not reachable ($n = 21$ or 10%) or unwilling to participate ($n = 77$ or 35%). Among the 74 remaining willing and eligible women (34%), we selected 60 women (30 Japanese, 30 Whites) to obtain a similar distribution of BMI in the two ethnic groups.

Participants underwent anthropometric measurements, a whole-body DXA scan and a fasting venous blood collection at the University of Hawaii Clinical Research Center and completed a brief self-administrated questionnaire on current use of dietary supplements and medications. Out of the 60 women, 48 also agreed to participate in an abdominal MRI scan at the University of Hawaii and Queen's Medical Center MR Research Center. The Institutional Review Boards of University of Hawaii and Queen's Medical Center approved the study protocol, and all participants signed an informed consent.

DXA and anthropometric measurements

Participants first visited the University of Hawaii Clinical Research Center for a series of examinations. A whole-body DXA scan (GE Lunar Prodigy, Madison, WI, USA) was performed to measure total and regional body fat mass in the trunk, arms and legs, as well as lean soft tissue mass and bone mineral content,²⁹ from which percent total fat (total fat mass divided by total body mass) was derived. The trunk-to-periphery fat mass ratio was calculated as an indicator of abdominal fat distribution by dividing the fat mass in the trunk by the sum of fat mass in the arms and legs. A certified radiographic technician operated the DXA according to a standard protocol. Calibration using a manufacturer's phantom was performed daily.

Anthropometric measurements included standing and sitting heights, weight, waist and hip circumferences, bi-acromial and bi-iliac breadths and chest depth. Leg length was obtained by subtracting sitting height from standing height, and proportional leg length (or leg-to-height ratio) by dividing leg length by height. Waist circumference was taken at two locations, that is, at the navel and immediately

above the iliac crest.³⁰ Hip circumference was measured at the widest area between waist and thighs, including buttocks. The breadth and depth measurements were obtained using a Lafayette Caliper.³¹ Each measurement was taken twice, and a third time if the two measures differed by >0.1 kg or by >0.5 cm, after which the average of the two closest values was used in the analysis.

Magnetic resonance imaging scan

Procedure and equipment. In total, 20 JA and 28 White women completed a one-time MRI scan within 1 to 13 weeks after the DXA scan on a research-dedicated 3 Tesla TIM Trio scanner (Siemens Medical Systems, Erlangen, Germany; software version VB13), using the body radio frequency coil for excitation and a six-element body matrix coil in conjunction with six elements from the multichannel spine coil for signal detection. The women were scanned in a supine position for approximately 30 min, with their abdominal area covered with the body matrix coil. Participants were instructed to hold their breath for 10–17 s during the gradient echo sequences in order to minimize respiratory motion artifacts.

First, sagittal and coronal localizer scans were performed to identify the liver and the specific lumbar spine position (L4–L5) of interest. Next, a series of axial triple-gradient-echo scans, using a fast low-angle shot (FLASH) sequence, was performed on the liver with the following set-up: 10 × 6 mm slices, 40 cm field of view, 256 × 256 resolution, time to echo (TE) = 2.4, 3.7 and 5.0 ms, time to relaxation (TR) = 160 ms, 25° flip angle, one average with radiofrequency spoiling and generalized autocalibrating partially parallel acquisition (GRAPPA) = 2. The time to echo values were optimized to acquire water and lipid signals in-phase, out of phase

and again in-phase.^{32–34} An additional set of lipid-only gradient-echo images with water suppression was obtained. Acquisition parameters were 35 cm field of view, 30 × 5 mm slices, TR/TE/TD (or difference in echo times) = 140/2.6/6000 ms, 70° flip angle, one average, two concatenations, 320 × 256 resolution, generalized autocalibrating partially parallel acquisition = 2, with two 80 mm suppression slabs with a 20 mm gap, parallel to the slices. All scans were immediately inspected for the presence of motion artifacts and repeated if any were visible.

Estimation of visceral/subcutaneous fat. Analyses were performed off-line using the National Institutes of Health program, Image J (<http://rsbweb.nih.gov/ij>). Each subject's cross-sectional water-suppressed image at L4–L5 spine position was segmented to a black and white image (with thresholding) using the binary function to emphasize the fat borders. The abdominal wall was traced manually first, and the total fat area (in mm²) was determined (Figure 1a). Next, the peritoneal wall was traced manually, and the visceral fat area (intrapertoneal, including fat inside internal organs) was determined, which was then subtracted from the first measurement to obtain the subcutaneous fat area (extra-peritoneal). Percent visceral and subcutaneous fat was then calculated by dividing each area by the abdominal area.

Estimation of percent liver fat. Using a Siemens Leonardo workstation, a circular region of interest (15–25 cm²) was defined in the lateral portion of the right lobe of the liver on the triple-echo fast low-angle shot images; care was taken to avoid the large vessels (Figure 1b). The signal intensities were determined for all three echo times. The signal intensities of the first and third echoes were averaged, yielding S⁺ (signal of water and lipid in-phase), and the signal intensity of the

Figure 1 Abdominal fat distribution assessed by magnetic resonance imaging. (a) Visceral and subcutaneous fat distribution at L4–L5: water-suppressed image (left) and binarized image with tracings for total cross-sectional area (green) and peritoneal membrane (yellow; right), differentiating the abdominal fat tissue (white) into the visceral component inside the peritoneum and the subcutaneous fat outside. (b) Liver fat assessment: abdominal images were obtained at three echo times –2.4 ms (in-phase, left), 3.7 ms (out of phase, center) and 5.0 ms (in-phase, right), from which average image intensity for liver fat estimation was measured in the right lobe of the liver (region of interest marked in circles), avoiding visible vessels.

second echo yielded S^- (signal of water and lipid out of phase). From these signal intensities, the relative fat content of the liver was calculated as follows:

$$F = (S^+ - S^-)/(1.7S^+ - 0.3S^-)$$

where the water content of the liver is assumed to be 70%.³⁴

Statistical analysis

All analyses were performed using the SAS Statistical Software, version 9.2 (SAS Institute, Inc., Cary, NC, USA). Demographic and lifestyle characteristics were compared between JA and White women using Wilcoxon rank-sum test for continuous variables or using the χ^2 -test of association for categorical variables. The main analysis included ethnic comparisons of indicators for total or overall adiposity (BMI and DXA total fat mass), central or abdominal adiposity (waist circumference, waist-to-hip ratio, DXA trunk fat mass and trunk-to-periphery fat ratio) and peripheral adiposity (DXA leg fat mass and arm mass). In addition, abdominal fat distribution into visceral vs subcutaneous fat components was assessed using the amount of MRI visceral and subcutaneous fat area at L4–L5 as percentages of MRI total abdominal area. Also, hepatic adiposity (MRI percent liver fat) was compared. Mean adiposity values were compared between JA and White women using analysis of covariance. The model assumptions were met for all models, although log-transformation was required for MRI percent liver fat.

Models were adjusted for age, or age and DXA total fat mass. DXA total fat mass was adjusted for because the study objective was to compare abdominal, visceral and hepatic adiposity at similar levels of overall adiposity. Because JA women had a significantly lower leg-to-height ratio and lower DXA leg fat mass, models were additionally adjusted for these variables to explore whether peripheral fat storage, indicated by these measures, explained the ethnic differences in abdominal, visceral and hepatic adiposity. Ethnic comparison of adiposity indicators was further stratified by three BMI categories (normal weight, overweight and obese), and heterogeneity across BMI categories was examined by including a cross-product term of ethnicity and BMI variables in the analysis of covariance model for each adiposity indicator, in which significance was determined by the P -value from the Wald test of the product term. A nominal level of $\alpha = 0.05$ was used for statistical significance. In addition, P -values corrected for multiple comparisons by computing false discovery rate, as shown below, are presented.³⁵ $P_{FDR} = \min(P_{(i+1)}, (m/i)P_{(i)})$ (where $P_{(i)}$ is the ranked P -value and m is the number of tests)

Results

By study design, mean age and BMI values were similar for the JA and White participants (Table 1). The upper range of BMI computed from measured weight and height was

Table 1 Characteristics^a of Japanese American and White female participants

	Japanese American (N = 30)	White (N = 30)	P-value
Age	63.6 (60.9, 65.7)	63.6 (61.2, 65.8)	0.87

^aData on participant characteristics obtained at the time of the adiposity measurements are presented. Median (range) for continuous traits and number of subjects (percent) for categorical traits are compared by ethnicity, with P -values from non-parametric Wilcoxon rank sum test and the χ^2 -test of association, respectively.

^bData from the baseline questionnaire (1993–1996) of the Multiethnic Cohort Study. Current or recent smokers were excluded from the study.

somewhat higher than the one based on self-report during recruitment ($18.5\text{--}35\text{ kg m}^{-2}$). Compared with White women, JA women tended to have a shorter standing height, lower leg-to-height ratio, lower hip circumference and a smaller chest depth. There was no significant difference between the two groups in weight, waist circumference or bi-acromial and bi-iliac breadths. JA women were also less likely than Whites to be currently using hormone replacement therapy, but were equally likely to be taking dietary supplements. Information available from the Multi-ethnic Cohort baseline questionnaire indicated that JA women had slightly fewer years of education and were less likely to be a former smoker than White women, but showed similar BMI gain since cohort entry, similar baseline dietary intake of fat or carbohydrate as percent calories and similar baseline physical activity (Table 1). The subset of women within each ethnic group who had undergone the MRI scan (20 JA and 28 White women) did not differ significantly from those who did not have an MRI, with regard to mean BMI, leg-to-height ratio, waist-to-hip ratio or DXA total and trunk fat mass (data not shown).

Table 2 compares the mean adiposity measures between JA and White women. All comparisons were adjusted for age, which provided essentially the same results as the unadjusted estimates in this study. Adiposity measures were

further adjusted for DXA total fat mass (last column in Table 2) to compare fat distribution between the two ethnic groups at similar levels of overall adiposity. DXA total fat was significantly positively correlated with all the regional adiposity indicators.

Compared with White women, and despite similar BMI and DXA total or percent fat mass, JA women had a significantly greater mean waist-to-hip ratio, measured either at the navel or immediately above the iliac crest, due to their lower hip circumference (Table 2). This difference remained statistically significant after adjustment for DXA total fat mass. Age-adjusted DXA trunk fat mass was similar in JA and White women but was greater in JA women after adjustment for total fat mass ($P=0.0004$). DXA leg fat mass was markedly smaller ($P=0.0007$) and trunk-to-periphery fat ratio markedly greater ($P=0.006$) in JA women compared with White women. These ethnic differences remained statistically significant after adjusting for total fat mass.

MRI measures were not significantly different between JA and White women in the subset of women who underwent this examination, although mean percent visceral fat and percent liver fat tended to be greater ($P=0.09$) in JA than in White women (Table 2). The difference in percent visceral fat reached statistical significance ($P=0.01$) after further adjusting for total fat mass, and the difference in percent liver fat

Abbreviations: DXA, dual energy X-ray absorptiometry; MRI, magnetic resonance imaging; P-FDR, P-value corrected for multiple comparisons using the false discovery rate method. ^aMean (95% confidence limit) is presented from analysis of covariance with adjustment for either (1) age or (2) age and DXA total body fat mass. Participants included 30 Japanese American and 30 White women for anthropometry and DXA measures and 20 Japanese American and 28 White women for MRI measures.

became of borderline significance ($P=0.06$). Using a cut point of 5.5% liver fat for diagnosis of fatty liver,^{36,37} the greater prevalence of fatty liver in JA was of borderline statistical significance, compared with White women after adjusting for total fat mass ($P=0.05$).

Results were similar when BMI instead of DXA total fat mass was used to adjust for total adiposity (data not shown): JA women showed a significantly greater waist-to-hip ratio, lower DXA leg fat, greater DXA trunk-to-periphery fat ratio and greater MRI percent visceral fat. However, in contrast to the adjustment for total fat mass, adjusting for BMI did not yield a difference in DXA trunk fat mass between JA and White women (14.6 kg in JA vs 14.9 kg in White women; $P=0.86$).

Adjustment for multiple comparisons did not change the significance of the findings but slightly attenuated the ethnic difference in MRI percent liver fat and fatty liver prevalence (Table 2, P -value corrected for multiple comparisons using the false discovery rate method, in the rightmost column).

Because JA women had a significantly lower leg-to-height ratio and lower DXA leg fat mass, adiposity analyses were further adjusted for either variable to explore if the ethnic differences are in part explained by these skeletal differences or reflect a greater tendency of White women to deposit fat in the legs. When adjusted for leg-to-height ratio, the ethnic patterns described above remained, but the differences were attenuated for MRI percent visceral fat (22.8% in JA vs 19.4% in White women; $P=0.20$) and for percent liver fat (5.1 vs 4.2%; $P=0.46$). Adjusting for DXA leg fat mass attenuated most of the differences, except for waist-to-hip ratio (measured at the navel, 0.95 vs 0.91; $P=0.0006$), and resulted in a significantly higher MRI percent subcutaneous fat in JA women (35.1 vs 29.0%; $P=0.04$).

Discussion

This cross-sectional study examined the body fat distribution of JA and White women of comparable BMI distribution, following the observation of a higher BMI-associated risk of diabetes and cancers among the former group in a large ongoing cohort study. JA and white women were found to have similar mean DXA total fat mass and waist circumference, but JA had a significantly smaller mean hip circumference and DXA leg fat mass. When regional adiposity indicators were adjusted for DXA total fat to compare proportional body fat distribution at similar levels of overall adiposity, greater MRI abdominal and visceral adiposity were observed among JA than in White women. JA women did not differ from Caucasians in measures of MRI abdominal subcutaneous fat and had only a nonsignificantly greater MRI percent liver fat and prevalence of fatty liver.

Our findings confirm previous studies that reported a high prevalence of central obesity among Asian ethnic groups.³⁸ In addition, our results are consistent with limited past data

that suggested a greater visceral fat deposition in young Asian-American women and in older Filipinas compared with Caucasians.^{20,21} VAT is a better predictor of metabolic syndrome than abdominal SAT^{9,39} and may explain, at least partially, the very high rates of Type 2 diabetes^{17,25} and colorectal cancer risk^{18,40,41} among Japanese and JAs. In addition to the physical proximity and connection of VAT to the liver, VAT appears to possess unique molecular properties with higher lipolytic activity and greater secretion of pro-inflammatory products compared with SAT.⁴²

We also examined percent liver fat by MRI, which has rarely been compared between Asians and non-Hispanic Whites from a single-source population. We found that JA women tended to have a higher percent liver fat and prevalence of fatty liver, compared with White women, although these differences did not reach statistical significance. This finding is consistent with an earlier study that detected a higher liver fat content among Japanese middle-aged men in Japan, compared with non-Hispanic White men in the US, despite a higher mean BMI in the latter group.²⁴ Using the cutoff value for percent liver fat of 5.5%, as suggested for the MRI-based diagnosis of fatty liver disease,^{36,37} 49% of JA and 26% of White participants in our study were likely to have fatty liver disease. This ethnic difference grew larger after adjusting for DXA total fat. Although we were unable to take into account the variation in fat content throughout the entire liver, our results, based on a partial assessment, further support the hypothesis that a greater tendency to accumulate hepatic fat may contribute to the higher risk of insulin resistance and dyslipidemia of JAs.^{24,43}

It is not clear why Asian Americans, who, on the average, have a lower overall adiposity, have a tendency to develop proportionally more abdominal and visceral adiposity. It may be related to Asians' lower capacity to store fat in peripheral regions, starting from an early age. We and others have observed higher central adiposity and lower peripheral adiposity in Asian women, as early as in adolescence and young adulthood.^{31,44} In the present study, we found that the higher abdominal adiposity and lower leg-fat mass in JA women were not entirely explained by their lower height, smaller leg-to-height ratio or lower chest depth. Other biological characteristics common to Asian men and women may contribute to their higher central adiposity and lower peripheral adiposity.

Our findings of greater abdominal and visceral adiposity among JA than White women were consistent across measurements, based on anthropometry, DXA and MRI. Waist-to-hip ratio was particularly good at reflecting the ethnic-specific fat distribution patterns and remained significantly different between the groups, even after adjustments for DXA total fat, proportional leg length or leg fat mass. Findings were similar but somewhat attenuated for waist circumference or waist-to-height ratio, as compared with the waist-to-hip ratio. Thus, simple measures of waist and hip circumferences appear to be a good indicator of the difference in abdominal fat between older JA and White women.

This study was limited to women, and the findings may not be generalizable to men. As one of the two previous studies in Asian Americans was also limited to women²¹ and the other reported greater VAT in Asian women but not in Asian men, compared with Whites,²⁰ it would be important to also examine men and include other Asian groups than JAs.

In our MRI study, one cross-sectional scan at L4–L5 was used to estimate the VAT and SAT areas, and the estimated VAT and SAT areas served as surrogates for abdominal VAT and SAT volumes, respectively. The L4–L5 level is the most commonly used demarcation for cross-sectional MRI or computed tomography scans for total abdominal fat distribution, and these measures have shown a good correlation with volumetric measurements from ‘multislice’ scans.^{29,45,46} However, one study found that the VAT area at L2–L3 or L1–L2 was better correlated than the VAT area at L4–L5 with the total VAT volume estimated from 35 continuous computed tomography images of the abdomen (from T10–T11 to L5–S1).⁹ In that study, women showed less variation in VAT and SAT measured at different cross-sectional levels than men. We also did not distinguish the deep vs superficial depots of the abdominal subcutaneous fat (DSAT and SSAT)—DSAT has been associated more closely with insulin resistance than SSAT or even VAT.^{47–49} African Americans, in particular, have been shown to have greater DSAT but less VAT than Whites, which makes the information on the sub-depots of the subcutaneous fat important for this ethnic group with relatively higher insulin resistance.⁴⁹ However, in contrast to people of African ancestry, studies of Asians and Whites have shown a good correlation between VAT and metabolic risk,²⁴ suggesting that a bias from lack of data on SAT layers is less likely.

Despite some potential limitations, this preliminary study assessed a large number of direct and indirect indicators of overall, abdominal, visceral and hepatic adiposity in understudied Asian-American women. The strong and consistent pattern that emerges of greater proportional abdominal and visceral adiposity among JA women compared with their White counterparts with similar BMI or total fat may be an important factor that contributes to their higher risk of diabetes and obesity-related cancers.
