Abstract

Background: Exhaled nitric oxide (F_ENO) measurements may help to highlight when inhaled corticosteroid (ICS) therapy should or should not be adjusted in asthma. This is often difficult to judge. Our aim was to evaluate a decision-support algorithm incorporating F_ENO measurements in a nurse-led asthma clinic.

Methods: Asthma management was guided by an algorithm based on high (>45ppb), intermediate (30-45ppb), or low (<30ppb) F_ENO levels and asthma control status. This provided for one of eight possible treatment options, including diagnosis review and ICS dose adjustment.

Results: Well controlled asthma increased from 41% at visit 1 to 68% at visit 5 (p=0.001). The mean fluticasone dose decreased from 312 mcg/day at visit 2 to 211mcg/day at visit 5 (p=0.022). There was a high level of protocol deviations (25%), often related to concerns about reducing the ICS dose. The % fall in F_ENO associated with a change in asthma status from poor control to good control was 35%.

Conclusion: An F_ENO-based algorithm provided for a reduction in ICS doses without compromising asthma control. However, the results may have been influenced by the education and support which patients received. Reluctance to reduce ICS dose was an issue which may have influenced the overall results.

Keywords asthma control, exhaled nitric oxide, inhaled corticosteroid, primary care

Introduction

Using biomarkers to guide disease management offers the opportunity to improve clinical outcomes, particularly if changes in the biomarker are more sensitive and specific for disease activity than changes in symptoms. This is true for exhaled nitric oxide (F_ENO), which is a surrogate measure of eosinophilic inflammation.¹ Importantly, eosinophilic airway inflammation is usually steroid-responsive,^{2,3} and F_ENO may be used to predict steroid responsiveness.^{4,5} Against this background, randomised trials have explored whether inhaled corticosteroid (ICS) dose adjustment based on F_ENO will improve outcomes.⁶⁻¹⁰ Some of these studies have been reported after the present study was commenced.^{7,8,10} Overall,

they have yielded inconsistent and somewhat disappointing outcomes, in contrast to proof-of-concept studies in which sputum eosinophil counts have been shown to improve asthma management.^{11,12} In one study, asthma control was maintained on significantly lower doses of ICS (40% less) in patients whose requirements were based on F_ENO, compared to a group whose dose was adjusted using a symptom-based algorithm.⁶ In other recent studies, no significant differences in asthma control were achieved when F_ENO was added to well organised conventional asthma management;^{7,10} this may reflect the fact that regular contact with patients together with easy access to appropriate medications are more important than the use of a biomarker.

Increasingly, asthma is being managed by nurse practitioners in association with primary care physicians. Local or international guidelines which focus on patient-reported symptoms form the basis for management, but it is recognised that symptoms are non-specific and multifactorial, and may be difficult to interpret. Assessing the need for changes in inhaled drug therapy can be challenging, and in theory at least, objective measurements of underlying disease activity, independent of symptoms, would be beneficial.

In a recent study, the feasibility of obtaining $F_{E}NO$ measurements in primary care has been confirmed.¹³ Here, we evaluated the utility of using $F_{E}NO$ levels in an unselected population of patients with a diagnosis of asthma in a primary care setting. The aims were two-fold: firstly, to assess whether an open $F_{E}NO$ -based protocol – similar to, but less resource-intensive than those used in previous randomised controlled trials – could be applied in the primary care setting, and what the impact on asthma outcomes would be; and secondly, to evaluate the practical issues associated with using and interpreting $F_{E}NO$ levels in a nurse-led asthma clinic.

Methods

Subjects

Patients with new onset asthma symptoms of six weeks' duration or longer or with previously diagnosed asthma were recruited. The setting was a primary care practice comprising 15,500 patients served by 11 general practitioners (GPs) in Dunedin, New Zealand. Patients with significant cardiac or other respiratory disease (including COPD), or other important co-morbidities were excluded. Smokers and recent ex-smokers (<6 months) were also excluded due to the confounding effect of smoking on $F_{E}NO$ measurements.¹⁴

Study design

This was an open, uncontrolled study designed to apply the findings of an earlier randomised controlled study⁶ in a primary care setting. At the initial assessment, inclusion and exclusion criteria were reviewed. For patients not taking ICS, each was commenced on inhaled fluticasone (Flixotide, GSK, Greenford, UK) at an initial dose of 250mcg/day via a spacer (Volumatic, GSK, Greenford, UK). For patients already taking ICS, they continued on the same drug in accordance with an equivalence protocol (see Table 1).

Patients were reviewed at three-monthly intervals for a total of 12 months (5 visits). At each visit, self-reported compliance with ICS therapy was ascertained and the need for any courses of oral prednisone was recorded. Asthma control was assessed on the basis of the "Three Questions"; i.e. "Over the last week 1. Have you had difficulty sleeping because of your asthma symptoms (including cough)? 2. Have you had more than your usual asthma symptoms during the day (cough, wheeze, chest tightness or

Table 1. Steps for ICS dosing. The conversion table provided equivalent doses for each of the inhaled corticosteroid and combination ICS/LABA preparations available in New Zealand at the time of the study.

Step	Fluticasone (mcg) (Flixotide/Seretide)		Budesonide/Beclomethasone (mcg) (Pulmicort/Symbicort/Beclazone)	
	Total daily dose	Twice daily dosing	Total daily dose	Twice daily dosing

3	500	250	800	400
4	1000	500	1600	800

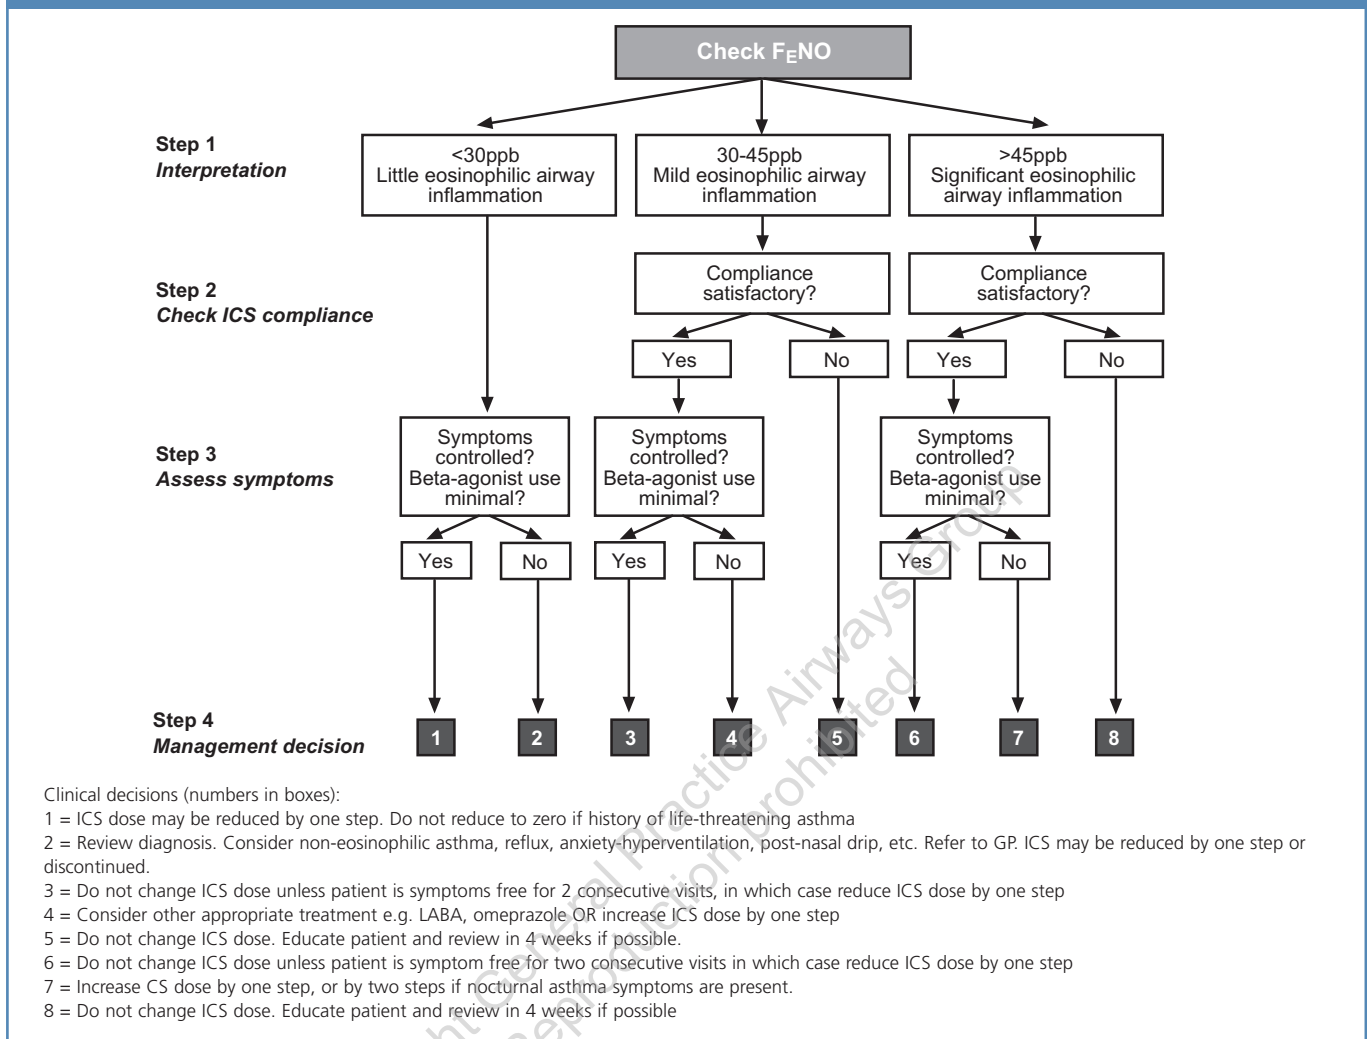

breathlessness)? 3. Has your asthma interfered with your usual activities (e.g. housework, work/school)?"¹⁵ A zero score is highly predictive of well controlled asthma.¹⁶ Where one or more of these questions was answered "yes" then asthma was deemed to be not well controlled. A recent increase in short-acting beta-agonist bronchodilator use compared to usual was also used as a marker of suboptimal asthma control. An $F_{E}NO$ measurement and spirometry were obtained.

Treatment was then adjusted according to the treatment algorithm in Figure 1. The algorithm specifically included options additional to ICS dose adjustment. The ranges for high, intermediate and low $F_{E}NO$ levels were >45ppb, 30-45ppb and <30ppb, respectively. These cut-points were based on data available at the time the study was designed. These indicated that levels of >47ppb are associated with steroid-responsiveness⁵ or the potential for relapse in asthma control when ICS therapy is reduced or withdrawn,¹⁷ and that the upper limit of "normal" for patients with stable asthma is 33ppb.¹⁸ Thus 45ppb and 30ppb were chosen as cut-points. The dosing steps for ICS are shown in Table 1. At any visit, the patient's GP was permitted to over-ride the treatment algorithm on the basis of clinical judgment. Reasons for any departure from the algorithm were recorded. Patients were permitted access to the clinic nurse throughout the study, and where necessary additional clinical visits were arranged.

Study measurements at each visit

$F_{E}NO$ was measured according to current guidelines¹⁹ using a NIOX MINO electrochemical analyser²⁰⁻²² or a NIOX chemiluminescence analyser (both Aerocrine, Solna, Sweden). The latter was available at the Research Unit, 5km. from the Health Centre, but was used only when there was technical failure of the NIOX MINO. To validate $F_{E}NO$ results, the sensors from the NIOX MINO device were tested against a calibrated standard, and where appropriate, a correction factor was applied to take account of signal drift. Spirometry

Figure 1. Decision algorithm in relation to compliance with ICS treatment, F_ENO levels and asthma control.

was performed according to accepted standards using a Spiro USB spirometer (Micro Medical, Kent, England).

The study received ethical approval from the Lower South Island Ethics Committee, and each participant gave written informed consent. Each GP participated in a start-up meeting, but thereafter further directions regarding the conduct of the study were not given.

Analysis

The primary study end-point was asthma control, recorded as yes/no for well-controlled asthma. The secondary study end-point was the dose of ICS at each visit and over the 12-month follow-up interval. Comparisons were made between ICS use during the 12 months prior to study entry for those patients who were not steroid-naïve, using individual prescription and pharmacy records. All doses of ICS are reported as fluticasone equivalent, where 1mcg fluticasone is equivalent to 2mcg of beclomethasone or budesonide. Clinical decisions made at each study visit were retrospectively assessed by JOC and DRT independently of the nurse (CMM) and GPs who undertook

day-to-day study monitoring, after the last patient had finished the study. Statistical analysis was by paired t-tests and analysis of variance as appropriate. The proportions of patients with well-controlled asthma at each study visit were compared using McNemar’s test.

Results

One hundred and thirty-one patients were entered into the study. Of these 14 did not wish to be treated with inhaled corticosteroids, six subsequently withdrew consent, 23 did not attend for follow-up, four developed other medical conditions, four were deemed to have a respiratory condition other than asthma, and two had asthma which was too unstable to permit further participation. Thus, 78 patients with a diagnosis of asthma completed the study. Their baseline data are summarised in Table 2.

Asthma control

The proportion (%) of patients with controlled and uncontrolled asthma at each study visit, stratified by steroid

Table 2. Baseline data. Asthma control (yes/no) was determined according to the "Three Questions" questionnaire (15). FEV₁ = forced expiratory volume in one second; ICS = inhaled corticosteroid; LABA = long acting beta-agonist.

Parameter	
n	78
Sex (Male:Female)	39:39
Mean age (years, range)	42 (11-75)
Ex-smokers	19 (24.4%)
Prior use of ICS (n)	56
LABA use at entry	14 (18%)
FEV ₁ % predicted	83.6 (SD 21.9)
Poorly controlled asthma at entry	46 (59%)

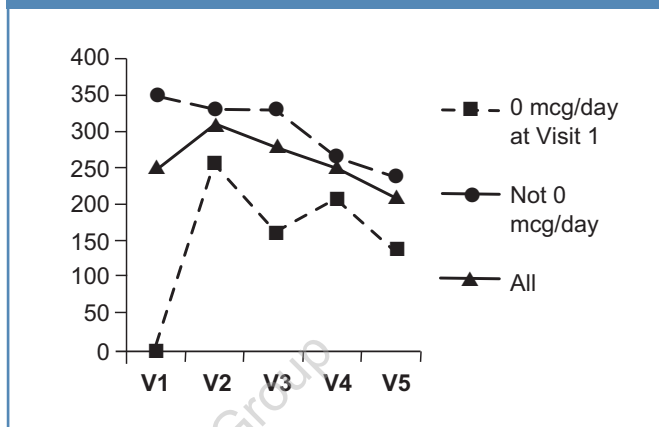

use at visit 1, is shown in Table 3. Overall, there was a significant reduction in the number of patients with uncontrolled asthma between visit 1 and visit 5 (p=0.0013). Between individual visits the change was significant only between visit 1 and visit 2 (p=0.002); thereafter the between-visit changes were not statistically significant. Only two patients required a total of three courses of oral prednisone during the study.

ICS use

Twenty-two patients (28.2%) were not receiving ICS at the time of entering the study. In those who were taking ICS and for whom full pre-study data were available (n=48), the calculated mean daily dose of ICS during the 12 months prior to study entry, based on prescription and pharmacy records, was 352mcg/day (fluticasone equivalent) [95% C.I.: 303, 402]. Over the entire 12-month study interval the mean daily dose in these 48 patients was 269mcg/day [95% C.I.: 209, 330; p=0.006]. The mean daily dose at the final study visit in these same patients (n=48) was 195mcg/day [95% C.I.: 146, 243; p<0.001 for comparison with 12 months prior to study entry].

For all 78 patients the mean daily fluticasone dose over the 12-month study interval was 267mcg/day [95% C.I.: 219,

Figure 2. Mean dose of fluticasone or equivalent (µg/day) at each study visit. The data are stratified into those who were steroid naïve at study entry (n=22; squares) and those who were already receiving inhaled corticosteroid therapy (n=56; circles).

314]. There was a progressive decrease in ICS dose requirements throughout the study, from a maximum of 312 mcg/day at visit 2 [95% C.I.: 253, 371] to 211mcg/day at visit 5 [95% C.I.: 165, 258]. The reduction in fluticasone dose over time was highly significant (p=0.022) (see Figure 2). Four patients discontinued ICS treatment altogether without adverse effect.

Subgroup analyses: high F_ENO

There were 39 patients whose F_ENO was high at visit 1 (>45ppb). The F_ENO remained high at visits 2, 3, 4, and 5, in 15, 15, 13 and 16 patients, respectively, although in only four patients were the F_ENO levels >45ppb on all five occasions. The changes in mean ICS dose requirements and asthma control at each visit for these patients are shown in Table 4.

The mean reduction in F_ENO in patients whose F_ENO was >45ppb at any visit who went from poor control to good control at the next visit (and for whom complete data were available; n=29) was 49.3ppb [95% C.I.: 27.1, 71.4], equivalent to a reduction in F_ENO of 35.2% [95% C.I.: 13.0, 57.4]. On the other hand, on those occasions when F_ENO was high and asthma was poorly controlled at that visit as well as at the subsequent visit

Table 3. Proportion of patients with well controlled asthma at each study visit. The study population is further stratified into those who were taking (n=56) or not taking (n=22) inhaled corticosteroid treatment at study entry. P values are for the significance of the change between visit 1 and visit 5.

	Visit 1	Visit 2	Visit 3	Visit 4	Visit 5	p
All patients (n = 78)	41.0% (32/78)	72.7% (48/66)	53.5% (38/71)	75.8% (50/66)	67.6% (50/74)	0.001
Not taking ICS treatment at study entry (n = 22)	9.1% (2/22)	79.0% (15/19)	65.0% (13/20)	77.8% (14/18)	60.0% (12/20)	0.002
Taking ICS at study entry (n = 56)	53.6% (30/56)	70.2% (33/47)	49.0% (25/51)	75.0% (36/48)	70.4% (38/54)	0.072

Table 4. Changes in ICS dose and asthma control in those patients who had a high F_ENO (>45ppb) at visit 1 (n=39). These data do not include patients whose F_ENO was >45ppb for the first time at visit 2 to 5 inclusive. Figures in brackets are 95% confidence intervals. * This included 18 patients whose ICS dose at visit 1 was zero.

	Visit 1	Visit 2	Visit 3	Visit 4	Visit 5
Number with F _E NO>45ppb at visit 1, with follow-up numbers	39	34	35	33	36
Mean F _E NO (ppb)	101.4 [86.6, 116.1]	54.9 [42.0, 67.9]	50.3 [41.0, 59.6]	44.8 [35.6, 54.0]	59.5 [46.9, 72.1]
ICS dose (mcg/day)	182* [116, 248]	352 [260, 444]	332 [231, 434]	311 [221, 402]	246 [168, 323]
Asthma not controlled (%)	69.2 (27/39)	26.5 (9/34)	42.7 (15/35)	21.2 (7/33)	38.9 (14/36)

Table 5. Changes in ICS dose and asthma control in those patients who had a low F_ENO (<30ppb) at visit 1. Figures in brackets are 95% confidence intervals.

	Visit 1	Visit 2	Visit 3	Visit 4	Visit 5
N	23	19	21	22	22
Mean F _E NO (ppb)	21.3 [19.0, 23.5]	31.6 [21.6, 41.5]	23.6 [17.1, 30.1]	25.7 [20.0, 31.4]	26.8 [19.7, 33.8]
ICS dose (mcg/day)	376 [303, 448]	206 [125, 287]	227 [144, 310]	190 [125, 255]	159 [96, 221]
Asthma not controlled (%)	30.4 (7/23)	26.3 (5/19)	42.9 (9/21)	31.8 (7/22)	22.7 (5/22)

(n=10), the mean reduction in F_ENO was less: 20.7ppb [95% C.I.: 5.0, 36.4], equivalent to 24.1% [3.9, 44.3].

Subgroup analyses: low F_ENO

There were 23 patients who had low F_ENO at visit 1 (<30ppb). The changes in asthma control and mean ICS dose requirements at each visit for these patients are shown in Table 5. Of the 23, only seven (30.4%) had poorly controlled asthma at visit 1. The number of patients with low F_ENO increased during the study to 27, 30, 33 and 32, at visits 2, 3, 4, and 5, respectively. F_ENO remained low throughout the study interval in only six. The mean reduction in F_ENO in patients whose F_ENO was <30ppb at any visit and who went from poor control to good control at the next visit (and for whom complete data were available; n=22) was 2.2ppb [95% C.I.: -1.4, 5.8], equivalent to 5.4% [95% C.I.: -9.2, 20.1], suggesting that factors other than airway inflammation

were responsible for the poor asthma control status.

Clinical decisions

There were 355 formal decision points in relation to the management algorithm during the study. Of these, 90 were discrepant (25.4%) – i.e. the decision made departed from the decision prescribed by the treatment algorithm – of which 23 (25.6%) were independently deemed to have been appropriate and 67 (74.4%) were considered inappropriate. Based on the clinical notes, these decisions were further classified and are reported in Table 6. The over-riding factors are listed in Table 7. The proportion of inappropriate decisions occurring in association with a high or low F_ENO did not differ (15.3% and 19.3%, respectively).

Table 6. Direction of dose adjustment for ICS on those occasions when the decision made was not what was prescribed by the treatment algorithm.

Inappropriate decision making regarding ICS dose	N (total = 90)
Should have been reduced but was not	30 (33.3%)
Should have been increased but was not	17 (18.9%)
Should have remained unchanged but was reduced	10 (11.1%)
Should have remained unchanged but was increased	26 (28.9%)
Unclear	7 (7.8%)

Table 7. Over-riding factors which operated at 90 decision points when the decision made was not what was prescribed by the treatment algorithm, arranged by category.

Decision	Appropriate	Inappropriate
Trend issues: falling F _E NO	2	0
Trend issues: rising F _E NO	4	3
Safety concerns	5	13
Confounding by external decision making	0	30
Patient preference, unspecified	1	12
Compliance issues	2	5
Indeterminate	9	4
Total	23	67

Discussion

In this open, uncontrolled study in a primary care setting, the use of a treatment algorithm based on $F_{E}NO$ measurements resulted in an overall increase in the number of patients with well-controlled asthma (from 40% to 70% approximately). Although the magnitude of the change was greatest in the steroid-naïve group and was achieved during the first three months of treatment, it was still identifiable in the steroid-treated group, although this was of borderline statistical significance. Regression to the mean may have influenced these trends. However, the improved asthma control also coincided with a progressive reduction in the dose of ICS, notably in patients already being prescribed ICS treatment (a 44.6% fall). The magnitude of effect for these outcomes is similar to those previously reported in a blinded randomised controlled trial.⁶ Although achieving well-controlled asthma in approximately 70% of patients may seem less than ideal, our results are similar to those in the so-called GOAL study in which 60-70% of patients achieved well-controlled asthma using a treatment strategy involving progressive step-up in ICS dose.²³ Thus, the use of the present algorithm appeared to achieve clinical benefits, and the primary aim of the study was fulfilled.

However, the interpretation of these results needs to be cautious. Deliberately, there was no control group; therefore, it is possible that the positive outcomes did not result from using the $F_{E}NO$ -based protocol *per se* but from increased contact between patients and the asthma nurse specialist. The level of support provided had not previously been offered – i.e. consultations prior to study entry were patient-initiated. In two recent studies investigating the effectiveness of $F_{E}NO$ ^{7,10} the impact of frequent contact with health professionals was highlighted as the likely reason for improved outcomes. In the study by Szeffler *et al.*⁷ in which adolescents with poorly controlled asthma received intensive education and support, most of the improvement in asthma control was achieved during the run-in. Depending on the measured outcome, the impact of nurse-led clinics compared to usual care is variable,²⁴⁻²⁷ suggesting that at least in part, the present results were attributable to using the $F_{E}NO$ -based protocol rather than simply increased contact with a health care professional. At the very least, it was our experience that $F_{E}NO$ measurements provided patients with more specific understanding of their asthma, often prompting a willingness to accept the diagnosis and the need for regular anti-inflammatory therapy.

$F_{E}NO$ -based treatment algorithms have varied with respect to $F_{E}NO$ cut-points; some have been two-tiered^{6,8} and others have been three-tiered^{8,9} or multi-tiered.⁷ In the present study, a three-tiered approach was adopted with cut-points of 30ppb and 45ppb. In our view, design features other than the

Difficulties Reluctance by clinicians to reduce or withdraw inhaled steroids despite objective evidence highlighting the appropriateness of doing so. This confounded the application of the treatment algorithm based on a biomarker.

Alternative methods The positive outcomes contained within this and other studies point to the benefits of regular patient contact with a nurse practitioner as a means of improving asthma outcomes

New questions Further studies are needed to explore whether there are specific subgroups of patients with asthma in whom the use of a biomarker is particularly helpful, for example obese patients with asthma.

Lessons Human behaviour and habits are as important as new technology in the management of disease.

cut-points for $F_{E}NO$ are more important in determining the efficacy of such algorithms. Firstly, the starting point for decision-making is critical. In the study by Szeffler *et al.*, decision-making was based firstly on symptom assessment and thereafter $F_{E}NO$ measurements were added – and conferred no benefits.⁷ In that study and the one reported by De Jongste *et al.*,¹⁰ low $F_{E}NO$ measurements were invariably “trumped” by symptoms, and in such circumstances no ICS dose reduction was possible. In the present study, the starting point for decision-making was the $F_{E}NO$ level (high, low or intermediate) followed by attention to clinical symptoms (see Figure 1). Low $F_{E}NO$ levels were acted upon even when symptoms were present (Figure 1; decision point no.2). Additionally, our algorithm also included treatment directives which went beyond adjusting the dose of ICS (e.g. decision point no.2: reconsider the diagnosis; and no.3: consider other treatment e.g. long-acting beta-agonist). This broader approach was considered important in the context of a “real world” study and may have contributed to better outcomes.

The study design was deliberately open, and permitted the algorithm decisions to be over-ridden by the GP. Somewhat surprisingly the frequency of these events was high: treatment decisions differed from what was specified at approximately 25% of the decision points (90/355). Of these 90 decisions, 25% (23/90) were considered to be appropriate. On the remaining occasions (67/90) when over-riding factors were considered to have been applied inappropriately, the reasons for doing so were variable (see Table 7). The majority (43/67, 64%) appeared to reflect a lack of confidence in relation to reducing the ICS dose, either on the part of the GP or the patient (designated “safety concerns”, “confounding by external decision making”). On 62.3% of these 67 occasions the ICS dose should have been reduced but was left unchanged or should have remained unchanged but was increased. This may have been because the algorithm decision

appeared counterintuitive or even risky. Concerns about the risks of reducing the ICS dose especially in a symptomatic patient also appear to have influenced the design of other studies.^{7,11} However, data show that the predictive value of a low F_ENO for subsequent loss of control with steroid dose reduction is high.²⁸ This message does not appear to have carried much weight. We concede that although the protocol violations in our study may have reduced the overall benefits of using F_ENO, it was unrealistic to expect the rigors of a randomised trial to be applied in day-to-day practice. In fact, despite the frequency of these “violations” a reduction in mean ICS dose was still achieved without compromising asthma control.

In a previous study, it was stated that “normalising” F_ENO is not possible in patients whose baseline F_ENO value is high.²⁹ Our results confirm that this is the case: among those with high F_ENO at visit 1, only four patients had subsequent values which were consistently lower than the cut-point of 45ppb. However, as seen in Table 4, despite consistently high levels at visits 2 to 5, in the majority of this subgroup asthma control was still achieved despite decreasing doses of ICS. This confirms that net changes in F_ENO in individual patients are more important than absolute values in relation to a specific cut-point. The magnitude of changes in F_ENO associated with improvement in asthma control status was similar to that reported by Michils et al.³⁰ In that study, the reduction in F_ENO associated with improved control was 40% or greater: in the present study it was 35.2% [95% C.I.:13.0, 57.4].

In summary, we have evaluated a decision-support algorithm for asthma management based on F_ENO measurements using a portable nitric oxide analyser²⁰⁻²² in primary care. The proportion of patients with poorly controlled asthma decreased, while simultaneously there was a progressive reduction in ICS dose requirements. The results may have been enhanced by regular contact with the asthma nurse. On the other hand, the benefits were obtained despite relatively frequent protocol “violations”. The outcomes obtained in patients with persistently high F_ENO levels suggest that fixed cut-points for F_ENO are less likely to be helpful than individually determined optimum changes. Although the weight of evidence in the literature does not support routine use of F_ENO to optimise asthma therapy, measuring F_ENO levels enables factors other than airway inflammation to be identified in patients with ongoing symptoms, and this can now be done easily in primary care.

Acknowledgements

The authors wish to thank the patients of the Mornington Health Centre for their participation in this study. They also acknowledge the active contribution of the nurses and doctors of the Health Centre including Eric Bradfield, Tony Fitchett, John Greaves, Elaine Harvey, Sharleen Johnston, Jenny Lewis, Tim Medicott, Peter Radue, Niranjana Sharma, Barry Turner, and Jonathan Woollych. The study was funded

through a Strategic Initiative Grant of the Dunedin School of Medicine (2005) and an unrestricted grant from Aerocrine AB, Solna, Sweden. The nitric oxide analysers were provided by Aerocrine, Solna, Sweden. Dr Hewitt was in receipt of the Tony Hocken Medical Research Fellowship of the Dunedin School of Medicine.

Conflict of interest declarations

The researchers received a grant of \$25,000 from Aerocrine AB, Solna, Sweden, a manufacturer of nitric oxide analysers to conduct this study. DRT has received lecture fees of \$2000 from Aerocrine AB, Solna, Sweden.
