ABSTRACT: Dispersion polymerization of styrene (S) and a cationic comonomer, 4-(vinylbenzyl)trimethylammonium chloride (VBA) was conducted in alkaline aqueous ethanol using various aromatic poly(amic acid)s (PAA) as stabilizers. The monodisperse particles were obtained in high yield using the optimum composition of solvent mixture depending on the PAA structure. By using a cationic comonomer (VBA), PAA was incorporated quantitatively into the particles. On the other hand, using cationic methacrylates as a comonomer, PAA was not incorporated effectively. The imidization of PAA on the particles proceeded with acetic anhydride and 4-(dimethylamino)pyridine to form PS-polyimide (PS-PI) particles. The PS-PI particles were maintained in spherical shape by the thermal treatment up to 240 °C. PI hollow particles were also obtained by washing PS-PI particles with toluene. KEY WORDS Dispersion Polymerization / Poly(amic acid) / Polyimide / Hollow Particle / Thermal Stability /

Dispersion polymerization is a versatile method for preparation of monodisperse polymer particles in the 0.5–10 μm size range. Especially the polymerization of styrene and methyl methacrylate has been extensively studied in polar media.¹ To disperse particles stably, a suitable steric stabilizer was used, such as polyethylene oxide,² polyvinylpyrrolidone,³ poly(2-ethyl-2-oxazoline),⁴ hydroxypropyl cellulose,⁵ and poly(acrylic acid).⁶

Aromatic polyimides (PI) are the most useful super engineering plastics which exhibit excellent thermal, electrical, and mechanical properties, and have been used widely in aerospace, electronics, and other industries. They are generally prepared through a two-step procedure by the ring-opening polyaddition of aromatic diamines to aromatic tetracarboxylic dianhydrides giving poly(amic acid)s (PAA), followed by thermal cyclodehydration.^{7,8} Since PAA has pendant carboxylic acids and is soluble in potassium carbonate aqueous ethanol solution, it would work as a steric stabilizer for dispersion polymerization. In the previous

study, we shortly reported the dispersion polymerization of styrene (S) using an aromatic poly(amic acid) (PAA **2a**) in an aqueous ethanol medium.⁹ After the polymerization, PAA was easily converted to polyimide to yield PS-PI particles (Scheme 1). Thus PAA would play two important roles, *i.e.*, a steric stabilizer during polymerization, and improvement in mechanical and thermal properties of particles by means of imidization of PAA. For this purpose, PAA must be incorporated into the particles effectively. In general dispersion polymerization, most of steric stabilizer was not incorporated into the particles. To incorporate it into particles effectively, reactive stabilizers having polymerizable group¹⁰ or radical transfer agent (mercapto group)¹¹ were used in the polymerization and stabilized particles even in their low concentration because they reacted with monomer and incorporated into the particles. In this study, a cationic comonomer, 4-vinylbenzyltrimethylammonium chloride (VBA), was employed in the dispersion polymerization. VBA could copolymerize with S to form cationic particles,

as a result, an anionic PAA could be adsorbed onto the particles by their electrostatic attraction.⁹

This article describes the various PAAs were employed as a steric stabilizer for dispersion polymerization and the preparation of PS-PI particles by dehydration of PAA on the particles.

EXPERIMENTAL

Measurements

Diameter of polymer particle was determined by a scanning electron microscope (JEOL JSM-588 scanning microscope). X-Ray photoelectron spectroscopic data were obtained on a RIGAKU XPS-7000 instrument with Al K α X-ray source (10 kV, 30 mA) at a take-off angle of 90°.

Materials

S was washed with aqueous NaOH and distilled under reduced pressure. 2,2'-Azobisisobutyronitrile (AIBN) was recrystallized from methanol. Poly(amic acid) (PAA) was prepared by the conventional ring-opening polyaddition of aromatic tetracarboxylic dianhydrides (**1a–1d**) with 4,4'-oxydianiline and purified by reprecipitation with water or methanol (Scheme 2).¹² Their inherent viscosities in *N,N*-dimethylacetamide (DMAc) at 30 °C were summarized in Table I. 4-Vinylbenzyltrimethylammonium chloride (VBA) was synthesized by the reaction of 4-vinylbenzyl chloride with trimethylamine¹³ and recrystallized from a mixture of acetonitrile and acetone (*v/v* = 1/1). Other reagents were obtained commercially and used as received.

Table I. Synthesis of poly(amic acid)^a

PAA	Viscosity ^b
	(dL/g)
2a	0.76
2b	1.20
2c	0.64
2d	0.81

^aODA (10 mmol) and tetracarboxylic dianhydrides **1a–1d** (10 mmol) were polymerized in 25 mL of DMAc at 12 °C for 1.5 h and at room temperature for 1 h. ^bInherent viscosity of **2a–2d** was measured in 0.5 g/dL of DMAc solution at 30 °C.

Dispersion Polymerization

Typical dispersion polymerization was conducted as follows. PAA **2a** (0.266 g; monomer unit: 0.42 mmol), VBA (0.212 g; 1.0 mmol), and potassium carbonate (0.104 g; 0.75 mmol) were dissolved in 100 mL of ethanol–water (80/20 = *v/v*). Into the solution, S (8.0 g; 76.8 mmol) and AIBN (0.16 g; 1.0 mmol) were added. The mixture was purged with nitrogen and stirred at 70 °C for 20 h with mechanical stirrer in nitrogen atmosphere. After removal of coagulated polymer by filtration, the resulting particles were purified with centrifugation using ethanol for three times.

Fluorine Content of the Particles

To determine the incorporation ratio of **2a** into the particles, the fluorine content of the particles was measured by the lanthanum alizarin complexone method as described in ref 14. Lyophilized polymer (10 mg) wrapped with filter paper (2 cm × 2 cm) was completely subjected to combustion under oxygen

atmosphere in a combustion flask containing deionized water (20 mL). The evolved fluorine was absorbed into the water. Into the fluorine anion solution (1.6 mL), 1 mL of 5% aqueous alfusone[®] solution (DOJINDO), 0.4 mL of 1.0 M acetate buffer (pH 5.0), 2 mL of acetone, and 5 mL of deionized water were added and the solution was allowed to stand at room temperature for 1 h. The absorption of solution was measured at 610 nm.

Imidization of PAA on the Polymer Particle

Lyophilized polymer particles (1.0 g) were suspended in a solution of 2.0 g of 4-(dimethylamino)pyridine (DMAP) in 15 mL of acetic anhydride (Ac₂O) and stirred at room temperature for 1 d. The suspension was poured into 50 mL of water and the particles were centrifuged, washed with ethanol twice, and dried under reduced pressure. PS-PI particles were recovered quantitatively (98%).

To separate the PI shell, the resulting particles were suspended in 30 mL of toluene and stirred at room temperature for 3 h and centrifuged with toluene twice.

RESULTS AND DISCUSSION

Dispersion polymerization of S and cationic comonomer, VBA was carried out using PAA (**2a**) as a steric stabilizer in an alkaline aqueous ethanol.¹⁵ Table II shows the results of polymerization changing the amounts of **2a** and water. When more than 23 mL of water was added, the size distribution was a little

broader (run no. 1) or a coagulated polymer was afforded (run no. 2). The polymerization using a small amount of water (15 mL) also induced the coagulation of polymer (run no. 6). Using 20 mL of water, monodisperse particles were yielded quantitatively (run no. 3). Solvent composition is well known to play a key role in the particle size. Generally, an increase in solvent polarity leads to formation of smaller particles, because more nuclei are produced in more polar medium. On the other hand, Paine reported the polymerization of styrene in a series of alcohols with a varying polarity. The particle size showed a maximum when the solubility parameter of medium was closed that of stabilizer.^{3b} In our case, the particle size increased with increasing amounts of water. Since the anionic PAA and cationic comonomer were used, nuclei formation must be complex.

The dispersion polymerization using less than 0.83 mmol of **2a**, gave monodisperse polymer particles in high yield (run nos. 7–9). When 1.25 mmol of **2a** was used, all polymer was coagulated during the polymerization (run no. 10). To estimate the amount of **2a** incorporated into the particles, the fluorine contents of particles were determined by the lanthanum alizarin complexone method. The particles were completely subjected to combustion and the evolved fluorine anion was detected by the lanthanum alizarin complexone reagent. Hence, all of the fluorine in the particles could be detected. Judging from the fluorine content of particles, most of **2a** was immobilized into the particles. To incorporate PAA into the particles, a cationic comonomer (VBA) was necessary for the polymerization.⁹ Other cationic comonomers were also examined. When 2-dimethylaminoethyl methacrylate, a methacrylate having tertiary amine, was used, no polymer particle was yielded during the polymerization (run no. 4). Although the polymerization using 2-(methacryloyloxy)ethyl]trimethylammonium chloride (MEA) afforded the particles, only 18% of **2a** were incorporated into the particles (run no. 5). VBA was copolymerized with S to form the cationic particles and then PAA was incorporated into the particles by their electrostatic attraction. Furthermore, ionic VBA itself might make the particles dispersed stably in the polymerization media. Since MEA was hydrophilic compared with VBA, MEA might mainly be polymerized in the solution. Consequently PAA was not incorporated into the particles.

The initial styrene concentration is important for the final particles size because the particle number is determined in very early stage. In general, particle size increases with the monomer concentration. Figure 1 shows the particle diameter against the amount of S in feed. The particle size increased with the amount of S from 0.59 μm to 1.5 μm. In all cases,

Figure 1. Effect of amount of S on particle size (**2a** = 0.42 mmol, VBA = 1.0 mmol, K_2CO_3 = 0.75 mmol, ethanol = 80 mL, and water = 20 mL).

^aPAA: 0.42 mmol, S: 8.0 g, VBA: 1.0 mmol, AIBN: 0.16 g, K_2CO_3 : 0.75 mmol, Solvent (H₂O + ethanol): 100 mL, 70 °C, 24 h. ^bYield of coagulated polymer during polymerization. ^cThe incorporated PAA was determined by fluorine content. ^dNot analyzed. ^eThe incorporated PAA was determined by the absorbance of supernatant after centrifugation at 295 nm.

monodisperse particles immobilized with **2a** (more than 88%) were obtained.

PAA was known to be hydrolyzed in alkaline solution. PAA **2a** was treated with the alkaline solution under the same condition as the polymerization in the absence of S, and its inherent viscosity was measured. Although the inherent viscosity of **2a** decreased 0.76 to 0.32 dL/g, the PAA treated with alkaline solution had still moderate inherent viscosity. Since most PAA was incorporated onto the particles during the polymerization, hydrolysis of PAA did not occur considerably.

Based on the optimum polymerization condition using **2a**, other PAAs (**2b–2d**) were employed as a stabilizer (Table III). Since **2b–2d** were slightly soluble in alkaline aqueous ethanol at room temperature, the PAA solutions were heated to 50 °C to dissolve them completely and the polymerizations were performed.

In case of **2a**, 20 mL of water was the optimum solvent composition. However, the particles using the other PAAs tended to be coagulated during the polymerization in the same solvent composition. Especially the polymerization using **2d** resulted in the coagulation of all the polymer particles. As volume of water increased to 30 mL, the polymer particles having **2b–2d** were obtained in quantitative yields. Since the solubilities of **2b–2d** were different from that of **2a**, the optimum solvent composition was also changed. The amount of **2b** or **2c** incorporated into the particles was measured by the absorption of supernatant after centrifugation and more than 90% of **2b** and **2c** were found to be incorporated into the particles.

The obtained particles were subjected to the subsequent heating at 60, 80, 100, 150, 250, and 280 °C for 30 min each *in vacuo*. PS particles without PAA were not kept in spherical shape by the thermal treatment because of the low T_g of PS (100 °C). On the other hand, the particles having PAA **2a** were maintained in spherical shape with some voids even after the thermal treatment (Figure 2b). The more rapid rise of temperature *i.e.*, at 60 °C for 30 min, at 100 °C for 1 h, at 200 °C for 1 h, and at 250 °C for 1 h made the particles fused together. PAA was gradually converted into PI even at low temperature. If the conversion of PAA was inadequate, the particles started fusing above 100 °C. While more PAA was converted into PI by the slow temperature rise, PI **3a** (T_g : 301 °C) shell protected the particles to maintain in the spherical shape even at high temperature.

The imidization of PAA on the particles (run no. 3) was also carried out using acetic anhydride and 4-(dimethylamino)pyridine at room temperature for 1 d and washed with ethanol. The fluorine content of particles was not changed after the imidization (before 274 μmol/g, after 281 μmol/g), meaning that no PI was desorbed from the particles. Although the particle size was not changed by the imidization, the particles were likely to be fused together, and some gel like materials existed on the surface (Figure 2c). Even after heating at 240 °C for 2 h *in vacuo*, some PS-PI particles were kept in their spherical shapes.

The atomic ratio of fluorine to carbon of the PS-PI particles determined by XPS was 35.9×10^{-3} , which was much larger than that determined by the lanthanum alizarin complexone method ($F/C = 3.56 \times 10^{-3}$). This means that PI was mainly located at the particles surface. During dispersion polymerization, hydrophilic PAA was localized on surface and hydrophobic PS was formed as a core polymer. Even if PI was formed by the dehydration of PAA, it would be still localized on the surface to yield core-shell PS-PI particles. Although PI content was only 2.8% weight of the particles (run no. 3), PI shell kept the

Figure 2. Scanning electron spectra of (a) PS-PAA particles (run no. 3; see Table II) (b) PS-PI particles prepared by thermal treatment. (c) PS-PI particles prepared by chemical imidization. (d) PI particles. (e) PI particles after heating at 240 °C for 2 h.

particle in spherical shape at 240 °C.

PI hollow particles were prepared by extraction of the PS-PI particles with toluene. By FT-IR measurement, almost PS was removed and characteristic absorptions of PI was detected.⁹ PI particles were shrunk and changed in shape (Figure 2d). The polyimide chains must have stress by the cyclodehydration of PAA. By treating with toluene, core polystyrene was removed and PI swelled a little. As a result, the polyimide chains might be reoriented to release the chain stress. Assuming that PI was localized to the surface on the PS-PI particles, the PI thickness could be calculated from the diameter and PI content at about

3.4 nm. Although PI thickness was very thin and the hollow particles were purified by centrifugation *i.e.*, the particles were subjected to the centrifugal force (21500 G), PI hollow particles were kept in the spherical shape mainly due to the excellent mechanical and thermal properties of polyimide. Furthermore they maintained in spherical shape even after heating to 240 °C *in vacuo* (Figure 2e).

In conclusion, PS-PAA particles were prepared by the dispersion polymerization of styrene (S) and VBA using various aromatic poly(amic acid)s as stabilizers in an aqueous ethanol. The monodisperse particles were obtained in high yield using the optimum com-

position of solvent mixture depending on the PAA structure. By using a cationic comonomer (VBA), PAA was incorporated quantitatively into the particles. The imidization of PAA on the particles proceeded with acetic anhydride and 4-(dimethylamino)pyridine to form PS-PI particles. The PS-PI particles were maintained in spherical shape by the thermal treatment up to 240 °C.
