Summary

In order to compare high and low oxygen affinity blood under conditions of severe respiratory failure, the effects of a high or low P_{50} were evaluated in two groups of newborn lambs (P_{50} , 20 mmHg versus 30 mmHg), under conditions of hypoxic hypoxia (F_{iO_2} , 10%) and hypercapnic hypoxia (F_{iO_2} , 10% and F_{iCO_2} , 10%). Data on cardiovascular function, blood gas parameters, and tissue oxygenation were collected under normoxic conditions and during severe hypoxia. During hypoxic hypoxia, a higher arterial oxygen content was noted in the high affinity group throughout the experiment; however, there were no significant differences detected in the remainder of the parameters studied. During hypercapnic hypoxia, the position of the oxygen dissociation curve did not cause any significant differences. When, however, hypercapnic hypoxia was compared to hypoxic hypoxia, there was a significant increase in cardiac output and myocardial contraction during hypercapnia.

Abbreviations

HbO₂, hemoglobin oxygen saturation
LV, left ventricle
LVET, left ventricular ejection time
PEP, pre-ejection period
ODC, oxygen dissociation curve
P $\bar{v}O_2$, venous oxygen tension

Recent studies in our laboratory have shown that a lower mixed venous oxygen tension (P $\bar{v}O_2$) in presence of high O₂ affinity red cells occurs in normoxemic newborn lambs and that severe anemic hypoxia is better tolerated in lambs with low affinity blood compared to high affinity blood (13, 26). A shift of the ODC to the right is believed to be advantageous at normoxia (13), anemia (26), and mild hypoxia (1, 12, 14, 18); however, it may be maladaptive under conditions of severe hypoxia (11). Early preterm newborn infants who have a high oxygen affinity blood (P_{50} , 18-19 mmHg) (3) frequently suffer from respiratory failure due to hyaline membrane disease. When the disease is severe they are often intubated and mechanically ventilated. Because hyperbilirubinemia is frequent in these infants, many of them are exchange transfused with adult blood (P_{50} , 27-28 mmHg).

In order to evaluate whether the manipulation of oxygen affinity could result in observable differences in cardiovascular function and tissue oxygenation during severe hypoxia, a study was planned to simulate severe respiratory failure in the neonatal period. Newborn lambs were chosen as an experimental model during the first 48 h after birth when their blood P_{50} is similar to that of early preterm newborn infants (18 mmHg) whereas the adult animal's P_{50} ranges between 32-40 mmHg (2, 3). The newborn lamb, after an exchange transfusion with adult sheep blood, would have its

P_{50} increased so that it is in the range of adult human blood (27 mmHg).

MATERIALS AND METHODS

Twenty-six mixed breed newborn lambs less than 48 h old were included in this study. Intramuscular diazepam was used as sedation (0.2 mg/kg as a loading dose, 0.1 mg/kg repeated at hourly intervals). Infiltration of lidocaine 2% provided local anesthesia at catheterization site. In an attempt to maintain constant metabolic demands, the animals were curarized with *d*-tubocurarine (0.2 mg/kg intravenously), half of this dose being repeated if necessary. They were intubated and mechanically ventilated. Rectal temperature was constantly controlled at $38.5 \pm 0.2^\circ\text{C}$.

Polyethylene catheters were positioned in descending aorta and right atrium. A Swan-ganz balloon catheter 5F was also placed in the pulmonary artery as described previously (13, 26). Statham P23Dc transducers provided pressure curves which were registered on a Grass model 7 paper recorder, giving heart rate, systolic, diastolic, and mean pressure values of both systemic and pulmonary circulations. The position of the catheters was determined by the morphology of the pressure curve. For the right atrium the catheter was advanced until the appearance of atrial extrasystoles. At the end of the experiment the position of all catheters were confirmed at autopsy. The lambs were divided in four groups, two of which had their high affinity red blood cells exchanged for low affinity red blood cells (Fig. 1). This was achieved by a two volume exchange transfusion (160 ml/kg) of fresh heparinized adult sheep blood. The first series of 12 experiments were carried out to compare the high and low oxygen affinity groups (six animals in each group, 1A and 1B) when being ventilated with a gas mixture of 10% O₂ and 90% N₂. Then another series of similar experiments were carried out with 14 animals (seven animal in each group, 2A and 2B) using a gas mixture of 10% O₂, 10% CO₂, and 80% N₂.

Oxygen content was measured in aorta, right atrium, and pulmonary artery samples using a Lex O₂ con, (Lexington Instrument Corporation, Waltham, MA). Throughout the study, the difference between the O₂ content of the pulmonary artery and the right atrium was never greater than 2%, indicating that there was no left-to-right shunt through the ductus arteriosus. Samples obtained from descending aorta and pulmonary artery were used to determine pH, PO₂, PCO₂, hemoglobin concentration and HbO₂ using instruments from Instrumentation Laboratory Inc. Lexington, MA (213 blood gas analyser tonometer, 208 gas mixing system, 182 co-oximeter). The expired gas was collected in a spirometer and its O₂ concentration was measured with an O₂ analyser apparatus S3A (Applied electrochemistry Inc. Sunnyvale, CA). Oxygen consumption per minute ($\dot{V}O_2$) could thus be determined. Cardiac output (\dot{Q}) was calculated applying the Fick principle and was reported to animal weight ($\text{ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$). Total pulmonary and

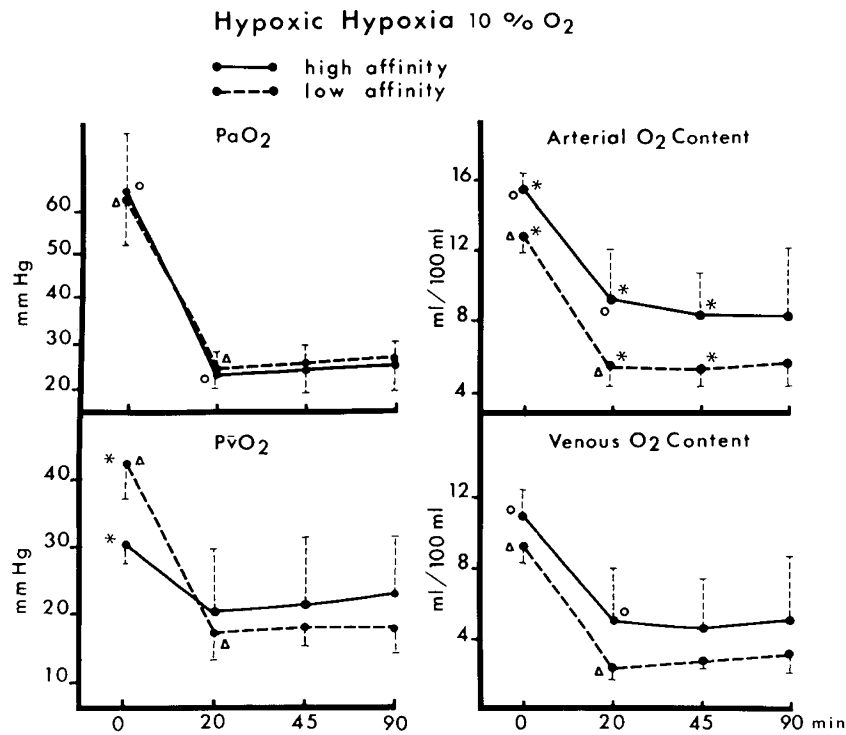

Fig. 2. The PaO₂, mixed venous O₂ pressure (PvO₂), arterial and venous O₂ content are represented at normoxia and after 20, 45, and 90 min of hypoxic hypoxia. The lines join the mean and ± standard deviation (S.D.) of the newborn lambs with either high or low affinity blood. The notations O and Δ represent significant differences between control and hypoxia values, whereas * indicates a significant difference between high and low affinity blood groups.

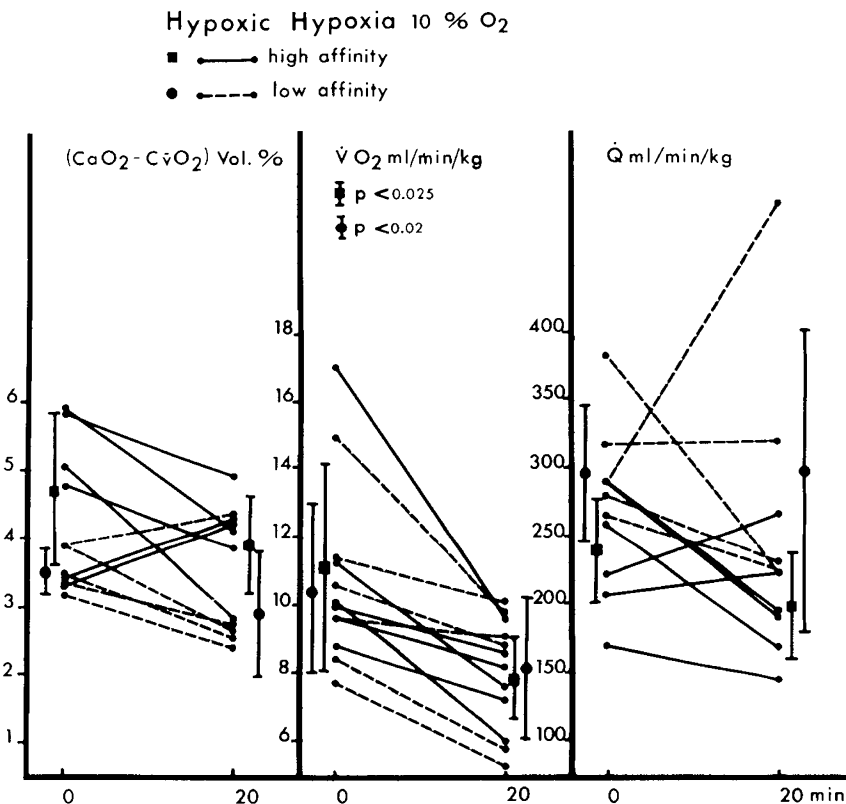

Fig. 3. The CaO₂-CvO₂, V̇O₂ and Q̇ are represented for each animal at normoxia and after 20 min of hypoxic hypoxia. The notations ● and ■ represent the mean ± standard deviation (S.D.).

Fig. 4. The Pao₂, mixed venous O₂ pressure (PvO₂), arterial and venous O₂ content are represented at normoxia and after 20, 45, and 90 min of hypercapnic hypoxia. The lines join the mean and ± standard deviation (S.D.) of the newborn lambs with either high or low affinity blood. The notations ○ and △ represent significant differences between control and hypoxia values, whereas the * indicates a significant difference between high and low affinity groups.

Fig. 5. The CaO₂-CvO₂, V̇O₂ and Q̇ are represented for each animal at normoxia and after 20 min of hypercapnic hypoxia. The notations ● and ■ represent the mean ± standard deviation (S.D.).

between the mean values at 20, 45, and 90 min of hypercapnic hypoxia. The $\dot{V}O_2$ and $CaO_2-C\bar{v}O_2$ decreased significantly and \dot{Q} increased significantly.

The mean heart rate increased from 197 ± 37 to 238 ± 18 ($P < 0.025$) for the high affinity blood and from 219 ± 34 to 243 ± 23 for the low affinity blood (nonsignificant). The pulmonary pressure increased markedly (from 30 ± 4 to 60 ± 8 mmHg, $P < 0.001$) whereas pulmonary resistance increases slightly (2300 ± 500 to 2800 ± 700 dynes·sec·cm⁻⁵, nonsignificant) in both affinity groups. The mean systemic pressure changed little, increasing from 75 to 85 mmHg. Systemic resistance decreased significantly ($P < 0.05$) for the high affinity group (6092 ± 1126 to 4096 ± 1109 dynes·sec·cm⁻⁵) and nonsignificantly for the low affinity group (5073 ± 1366 to 3897 ± 826 dynes·sec·cm⁻⁵). But when comparing high and low affinity groups there were no significant differences.

In hypercapnic hypoxia left ventricular dp/dt increased significantly from 3693 ± 1075 mmHg/sec to 5410 ± 433 with high affinity RBCs and from 4482 ± 1580 to 5805 ± 1445 with low affinity RBCs ($P < 0.05$). The left PEP/ET remained stable, 0.257 ± 0.054 to 0.261 ± 0.037 and 0.280 ± 0.059 to 0.308 ± 0.058 with high and low affinity blood respectively. There were no difference between the high and low affinity blood groups.

The stability of the preparation used in this study was controlled by measurements taken over a 12-h period in two normoxic animals. The S.D. of serial measurements taken every hour over this period was 4% of the mean for $\dot{V}O_2$, 10.5% of the mean for \dot{Q} and 8% of the mean for $CaO_2-C\bar{v}O_2$, the variation of the other parameters remains under 5% of the mean. As shown by greater S.D., the variability between our experimental animals during normoxia was more important. The S.D. was 23% of the mean for $\dot{V}O_2$, 23% for \dot{Q} and 24% for $CaO_2-C\bar{v}O_2$ and variations of the other parameters remained between 15–20%.

DISCUSSION

This study provides information on the influence of the position of the ODC upon the oxygenation of the newborn lamb under severe hypoxic hypoxia and severe hypercapnic hypoxia. The animals were lightly sedated, ventilated and curarized in an attempt to maintain constant metabolic demands. The use of sedated and ventilated newborn lambs certainly had its limitations. Cross *et al.* (5) reported that $\dot{V}O_2$ in nonshivering, nonpanting lambs less than 1-day-old was 12–15 ml·kg⁻¹·min⁻¹ under normoxic conditions and that it decreases to 6 ml·kg⁻¹·min⁻¹ under hypoxic conditions (Fio₂, 10–12%). Those values were similar to the $\dot{V}O_2$ found in this study. Also cardiac output values, as in this study, did not change under hypoxic conditions (5, 6). In other studies carried out with unsedated lambs during the first day of life, the reported $\dot{V}O_2$ and \dot{Q} were either similar (28) or slightly higher than the data reported in this study (4, 19). The differences are likely due to the lowered oxygen requirements of the mechanically ventilated newborn lambs reported in this study.

The biologic importance of differences or changes in ODC have been observed between mother and fetus, at altitude, and during hypoxia. The high oxygen affinity of fetal blood suggests that it is designed to facilitate oxygen uptake across the placenta. The comparisons of oxygen transport between different O₂ affinity blood in mammals as well as across the pregnant uterus have been reported by Metcalfe and his group (20, 21). These authors showed that an evaluation of tissue oxygenation can be made between high and low affinity blood, when the total O₂ consumption, O₂ content difference between arterial and venous blood as well as the P $\bar{v}O_2$ are determined. The important variable when evaluating oxygen delivery to the tissues is mixed venous PO₂. The concept that the level of mixed venous blood tension is a reliable index of tissue oxygenation has been supported by others (25).

In situations of compromised oxygen availability, such as occur in severe red cell mass deficits or poor arterial blood perfusion, a

lowered hemoglobin oxygen affinity is of benefit (9, 23, 26). The changes in oxygen hemoglobin affinity that have been described at moderate altitude remain controversial. It has been accepted by some that there is a decrease in erythrocyte O₂ affinity induced by altitude which facilitates oxygen unloading at the tissue level (1, 12, 14, 18). But Winslow *et al.* (27) concluded that this shift was offset by compensated respiratory alkalosis with the net results that the ODC position was similar to that of sea level humans. Yet, animals living at high altitude have a higher blood O₂ affinity than their lowland relatives (22). Also it has been shown that rat survival at high altitude (10,000 m) was increased with high affinity hemoglobin in circulation (11) and in a very recent report it was shown that humans having high affinity hemoglobin mutants were better adapted to moderate altitude (16). Thus under conditions of hypoxic hypoxia it may be of greater physiologic importance to have an increase in oxygen binding rather than an increase in oxygen unloading.

In this study, during hypoxic hypoxia, the significant differences noted between high and low affinity can be explained by the respective position of the oxygen dissociation curve. For the same amount of extraction the P $\bar{v}O_2$ in low affinity group is higher under normoxic conditions. At identical PaO₂, the O₂ contents of the high affinity groups are higher. But no physiologic differences could be demonstrated by these changes because cardiac output, $\dot{V}O_2$, and $CaO_2-C\bar{v}O_2$ between high and low affinity groups were not different. Also the absence of acidosis showed that the minimal O₂ requirements during hypoxic hypoxia were maintained irrespectively of the ODC position.

During hypercapnic hypoxia as expected, $\dot{V}O_2$ also decreased significantly; however, unlike the eucapnic group, cardiac output increased probably due to the highly stimulant effect of CO₂ on the autonomic nervous system (10, 17, 24). Therefore for the same decrease in $\dot{V}O_2$, $CaO_2-C\bar{v}O_2$ decreased significantly owing to the increased \dot{Q} . There is no clear explanation for the significantly high PaO₂ in the low affinity group seen during hypercapnic hypoxia. A similar phenomena had been observed by others in hypercapnic low birth weight newborn infants after exchange transfusion (15). A possible speculation is that this finding is the result of a difference in cardiac output as well as pulmonary perfusion.

Although there was a significant decrease in $\dot{V}O_2$ in all groups during severe hypoxia, myocardial function was not impaired as shown by the stable dp/dt in hypoxic hypoxia. In hypercapnic hypoxia the dp/dt increased in both high and low affinity groups. These findings go along well with the increase in \dot{Q} . It may well be that a mild hypercapnia by improving \dot{Q} could have a beneficial effect on tissue oxygenation which has been masked by the severe acidosis created by the degree of hypercapnia in this study.

There are several reports and studies which showed that the use of exchange transfusions increased the survival rate of infants of very low birth weight with severe respiratory distress syndrome (7, 8, 15). The cause of this decrease in mortality remains unclear. The present study shows that from an O₂ delivery point of view and myocardial function, the manipulation of red cell oxygen affinity is of no advantage nor disadvantage during severe respiratory failure of the newborn lamb.
