BACKGROUND: Current sustained lung inflation (SI) approaches use uniform pressures and durations. We hypothesized that gestational-age-related mechanical and developmental differences would affect the time required to achieve optimal lung aeration, and resultant lung volumes, during SI delivery at birth in lambs.

METHODS: 49 lambs, in five cohorts between 118 and 139 days of gestation (term 142 d), received a standardized 40 cmH₂O SI, which was delivered until 10 s after lung volume stability (optimal aeration) was visualized on real-time electrical impedance tomography (EIT), or to a maximum duration of 180 s. Time to stable lung aeration (T_{stable}) within the whole lung, gravity-dependent, and non-gravity-dependent regions, was determined from EIT recordings.

RESULTS: T_{stable} was inversely related to gestation ($P < 0.0001$, Kruskal–Wallis test), with the median (range) being 229 (85,306) s and 72 (50,162) s in the 118-d and 139-d cohorts, respectively. Lung volume at T_{stable} increased with gestation from a mean (SD) of 20 (17) ml/kg at 118 d to 56 (13) ml/kg at 139 d ($P = 0.002$, one-way ANOVA). There were no gravity-dependent regional differences in T_{stable} or aeration.

CONCLUSIONS: The trajectory of aeration during an SI at birth is influenced by gestational age in lambs. An understanding of this may assist in developing SI protocols that optimize lung aeration for all infants.

At birth, the fluid-filled fetal lung displays a high resistive state with a prolonged time constant (1–3). Lung aeration immediately after birth relies on the generation of sufficient driving pressure to move lung fluid distally and promote trans-epithelial fluid clearance (3). Preterm infants are often unable to generate the intrathoracic pressures needed to achieve this. A sustained lung inflation (SI), designed to deliver a prolonged positive driving pressure before normal tidal inflation, has been advocated as a

potential method of optimizing lung aeration at birth in preterm infants (4). To optimize aeration, both the duration (2,5) and applied pressure of the SI need to be sufficient to overcome the resistance of the lung (2,3). The role of SI pressure has been explored (6), but the factors influencing SI duration are poorly understood. To date, clinical trials of SI have used standardized predetermined fixed durations of 5–15 s, with conflicting results (7–13). This approach assumes a uniform aeration response in all individuals. Our group recently demonstrated that the aeration response of the lung and resultant aeration volume following SI delivery in 127-d gestation preterm lambs were highly variable, although reproducibly predictable, reaching a plateau at five time constants (1,2,6,14). This variability may account for the mixed results of SI in previous studies, and suggests that a uniform SI strategy may expose some recipients to inadequate aeration and others to excessive pressure, both with potentially harmful consequences (15).

Recent advances in electrical impedance tomography (EIT) have enabled monitoring of the aeration response of the lung from birth, allowing individual titration of the SI duration to the aeration response experimentally, with improved gas exchange and lung mechanics compared with a fixed 30-s SI (2,16). Although this approach offers more favorable lung aeration, it is currently a research tool only. Development of safe and effective guidelines for SI application in clinical practice requires exploration of factors that may affect the aeration response of the lung.

The mammalian respiratory system undergoes significant changes during fetal life, and the preterm lung is mechanically and developmentally different from the term lung. Gestational age (GA) may thus affect the aeration response of the lung following SI delivery at birth. We hypothesized that GA differences in the mechanical properties of the lung would significantly influence the time required to reach optimal (stable) lung aeration. Using EIT to individualize SI delivery,

in five GA cohorts of lambs between a pre-viable developmental state and term, we aimed to determine (i) the relationship between GA and the time to stable lung aeration; (ii) the resultant aeration (lung) volume; and (iii) the parameters that define the exponential temporal aeration relationship of the lung.

METHODS

The study was performed at the large animal facility of the Murdoch Children's Research Institute (Melbourne, VIC, Australia). The study was approved by our Animal Ethics Committee in accordance with National Health and Medical Research Council (Australia) guidelines.

Fetal Instrumentation

Lambs of date-mated Border-Leicester cross ewes, raised from the same flock and breeder, were delivered via Cesarean section, under general anesthesia, in five GA cohorts representing the spectrum of gestation-related developmental states from pre-viable to term: 118–120 d (pre-viable), 123–125 d (extreme preterm), 127–129 d (very preterm), 132–134 d (preterm), and 139–141 d (term). All ewes allocated to preterm cohorts received 11.5 mg of betamethasone 24 and 48 h before delivery. While on placental support the fetal head and neck were exteriorized, the carotid artery and external jugular vein were cannulated, and the trachea was intubated with an appropriately sized cuffed endotracheal tube (ETT) (17). Fetal lung fluid was passively drained (~15 ml/kg of estimated birth weight), to emulate conditions consistent with human birth, and the ETT was clamped (2). The thorax was exposed and a 32-electrode EIT belt custom-built for lambs (Swisstom AG, Landquart, Switzerland) was secured around the chest (18). A 10 s uncalibrated reference EIT recording of the unaerated lung was made to determine fetal (unaerated) values (19), and midazolam, ketamine and propofol sedation was administered intravenously before delivery, to suppress any spontaneous breathing that might initiate lung aeration and bias the results. After delivery, the lambs were weighed, placed supine, and midazolam and ketamine infusions were commenced to suppress spontaneous breathing for the remainder of the study. Physiological measurements were commenced before delivery of the SI. The total time between cord clamping and delivery of the first inflation was less than 60 s in all lambs.

Sustained Inflation

On unclamping the ETT, an SI was delivered using a Neopuff T-piece Resuscitator (Fisher Paykel Healthcare, Auckland, New Zealand) at a peak inspiratory pressure of 40 cmH₂O, fraction of inspired oxygen (FiO₂) of 0.3, and 10 l/min gas flow. The SI was delivered until 10 s after volume plateau on the uncalibrated EIT display, or for a maximum of 180 s (refs 2,16). The lung was held at a positive end-expiratory pressure of 8 cmH₂O for 3–5 s, the ETT was clamped, and the lamb was transferred to an SLE 5000 ventilator (SLE5000, SLE, South Croydon, UK) for ongoing positive pressure ventilation in volume-targeted mode.

Assessment of GA Model

To determine the mechanical properties and clinical relevance of the GA cohorts, and as part of another study evaluating the role of fetal lung development on expression of early biomarkers of ventilator-induced lung injury, positive pressure ventilation was continued using a standardized strategy of positive end-expiratory pressure of 8 cmH₂O, initial tidal volume of 7 ml/kg, inspiratory time of 0.4 s, maximum peak inspiratory pressure of 40 cmH₂O, and a rate of 60 inflations per minute. Continuous monitoring of peripheral oxyhemoglobin saturations (SpO₂), heart rate, arterial blood pressure, and rectal temperature (HP48S, Hewlett Packard, Andover, MA) ensured lamb's well-being throughout the study period. At 60 min, all lambs were ventilated with 1.0 FiO₂ for 3 min and

disconnected to atmosphere for 2 min, before an *in vivo* super syringe pressure–volume measurement was obtained to a maximum pressure of 35 cmH₂O (19). At the end of the study period, lambs received a lethal intravenous dose of pentobarbitone.

Autopsy was performed to obtain histological samples, in order to characterize the developmental state of the lung for each GA cohort. The right upper lobe was fixed at 20 cmH₂O in 4% paraformaldehyde, and three geographically standardized sites were sampled before further processing of the lung tissue. Histological examination was performed on hematoxylin and eosin-stained formalin-fixed lung sections. Post staining, a minimum of five fields of view (FOV) per site (total n = 15 FOV) were photographed per lamb (Leica Microsystems, Wetzlar, Germany), and the Image J software (20) was used to determine the percentage of space occupied by airway, alveolar wall thickness, and presence of hyaline membranes. All microscopy assessments were performed by a blinded investigator.

Measurements

Global and regional thoracic volume changes (ΔV_L) were measured continuously from 5 s before the SI using EIT (Swisstom Pioneer System and STEM software) at 50 frames/s. The EIT ΔV_L signal was displayed in real-time on a bedside computer monitor (Swisstom STEM software), using an anatomically correct image reconstruction algorithm for the lamb (18,19). Proximal airway pressure (P_{AO}) and flow at the airway opening were measured continuously from birth at 200 Hz using a Florian Respiratory Mechanics monitor (Acutronic AG, Hirzel, Switzerland) (17) in order to calculate dynamic compliance (C_{dyn}). Forced oscillation technique measurements were taken for the first 15 min and immediately after each blood gas analysis by superimposing a 5 Hz oscillatory pressure onto the ventilation waveform during positive end-expiratory pressure (2,21). Resistance (R_s) and reactance (X_s) were computed from the forced oscillation technique signals using the method of Dellacà and co-workers (2,22).

Data Analysis

Global and regional time-course changes in impedance from pre-aeration (immediately before SI) until the end of the SI were reconstructed using the manufacturer's IBEX software package (Swisstom AG), and the heart-beat-related impedance signals were removed as previously described (2). SI duration was determined directly from the time-impedance reconstructed data. The global ΔV_L from the pre-aerated state was calibrated to ml/kg using calibration coefficients derived from the static pressure–volume measurement (2). Relative ΔV_L within the gravity-dependent and nondependent regions was determined from the raw data. Previous work with our model identified an unequal weighting of lung tissue on computed tomography between the gravity-dependent and nondependent hemithorax permutations on each EIT cross-sectional slice, with 63% of all lung tissue pixels occurring in the dependent hemithorax (19). To account for this, and to determine relative regional volume state, ΔV_L data were weighted according to the known pixel contribution of each region to global volume, expressed as a fraction of the maximum volume potential in that region (19), with a value of 1.0 suggesting optimal aeration, a value <1.0 suggesting lower than expected aeration, and a value >1.0 suggesting relative overaeration in that region. Volume states in opposing regions of interest were then compared to determine the homogeneity of the aeration response within the lung.

To allow for the possibility that ΔV_L had not stabilized within 180 s, and to better describe regional patterns of change, three exponential models (one-phase; plateau followed by one phase; and two phase) were applied to the SI ΔV_L signals to predict the global and regional time to stable lung volume (T_{stable}) during each SI, defined as five time constants of the respiratory system (τ) (1). All models tested identified R^2 of 0.82–0.99. As there was no benefit of the more complex models, the simplest one-phase model was selected:

$y = y_0 + (y_{\text{plateau}} - y_0) \cdot (1 - \exp(-k \cdot x))$; where y_{plateau} = maximum ΔV_L , $y_0 = \dot{V}_L$ immediately before SI, x = time (s), k = reciprocal of τ . (1,2).

Statistical Analysis

The absolute difference between SI duration across gestations was not known. Previously, in 127-d steroid-exposed lambs of the same species and breeder, a mean (SD) of 78 (31) s was needed to achieve SI plateau (2). A feasibility sample of 10/group would detect a difference of 41 s between any two groups (power 0.8, alpha error 0.05). Data were tested for normality and analyzed using one-way ANOVA or two-way ANOVA, or linear regression as appropriate. All statistical and modeling analyses were performed with GraphPad PRISM 6 (GraphPad Software, San Diego, CA), and $P < 0.05$ was considered significant.

RESULTS

Fetal Characteristics

Forty-nine lambs were studied. In seven lambs, data analysis was limited to the SI only because of faulty equipment or incomplete data. As expected, birth weight increased with GA, $P = 0.003$, one-way ANOVA (Table 1). Apart from higher drained fetal fluid volumes in the 139-d cohort ($P = 0.002$), there were no other differences in the fetal characteristics. Eight lambs developed pneumothoraces (118 d, $n = 4$; 123 d, $n = 4$): one at 50 min of age and the remainder during the static super-syringe pressure-volume (PV) measurement. No other adverse events were noted.

Developmental Differences in the GA Cohorts

There were clinically predictable GA-related differences in lung mechanics (Figure 1) and histology (Figure 2). The more preterm lambs had lower X_{rs} and a higher oxygenation

index throughout, higher R_{rs} until 45 min of age, and poorer C_{dyn} from 10 min of age; all had P value < 0.05 according to Kruskal–Wallis test with Dunn's post tests. The more preterm cohorts had a lower proportion of alveolar spaces ($P < 0.0001$, one-way ANOVA), thicker alveolar walls ($P < 0.0001$), and a greater number of hyaline membranes ($P = 0.0007$) than the more mature lambs on histology.

SI Characteristics

SI duration decreased with increasing GA, $P = 0.0001$, Kruskal–Wallis test (Figure 3a). A SI volume plateau was not obtained by 180 s in 67% of the 118-d lambs and 80% of the 123-d lambs, despite the delivered SI being twice as long compared with the 139-d lambs (median 183 and 183 vs. 94 s). Global ΔV_L increased linearly with GA (Figure 3b), from a mean (SD) of 20 (17) ml/kg at 118 d to 56 (13) ml/kg at 139 d (linear regression, $R^2 = 0.96$, $P = 0.003$). There were no gestational differences in the relative volume state within the nondependent and dependent regions (Figure 3c), and all gestations had relative heterogeneity of aeration within the lung at the end of the SI (Figure 3d). Like volume state, there was wide variation across gestations, with the highest heterogeneity seen in the 127-d and 139-d cohorts, although neither were significant.

Modeled Time to Lung Volume Stability

T_{stable} was inversely related to GA in the global lung, the gravity-dependent, nondependent, left and right regions (Table 2). T_{stable} was more than three times longer in the 118-d and 123-d cohorts compared with the 139-d (Figure 4a)

aeration during a single SI at birth. By 60 s, the 139-d cohort had obtained 94% of final aeration, compared with only 73 and 67% in the 118-d and 123-d cohorts, respectively, $P < 0.0001$, one-way ANOVA with Tukey’s post tests. There were no differences in the modeled regional volumetric behavior (Table 2).

DISCUSSION

Achieving lung aeration at birth is essential to establishing effective ventilation. SIs are increasingly advocated for this purpose, but the influence of the developmental lung state on

this therapeutic maneuver is poorly understood. Our preterm lamb study evaluated the role of GA on initial lung aeration using an SI, the first to our knowledge to do so systematically in an appropriate model of the human lung. We found significant differences in the temporal behavior of lung aeration and absolute aeration volume, related to the gestational mechanical and developmental properties of the lung. Increasing prematurity was associated with slower aeration patterns and lower aeration volumes. Although this is an animal study, our findings have important implications for clinical practice. Clinical uses of SI have focused on

Figure 4. Predicted global and regional time to stable lung volumes (T_{stable}). **(a)** Predicted T_{stable} in the whole lung (global) by GA, calculated using a one-phase exponential model $y = y_0 + (y_{plateau} - y_0)(1 - \exp(-kx))$, where $y_{plateau}$ = maximum ΔV_L , $y_0 = V_L$ immediately before SI, x = time (s), k = reciprocal of time constant (τ). **(b)** Difference between actual delivered SI duration (maximum 180 s) and predicted T_{stable} . **(c)** Regional predicted T_{stable} within the right (dark gray dotted bar) and left (light gray dotted bar) hemithoraces and **(d)** nondependent (dark gray dotted bar) and dependent (light gray dotted bar) hemithoraces by GA. Figure 5. Volumetric behavior of the lung during the SI (maximum duration 180 s) normalized in each animal to global ΔV_L for 118-d (a), 123-d (b), 127-d (c), 132-d (d), and 139-d (e) GA cohorts. Solid line represents mean and dashed lines represent SD. GA, gestational age.

predetermined SI duration and driving pressures, without mandating differences in duration by GA. Such approaches are unlikely to optimize lung aeration within all individuals, and may create injurious conditions, especially if combined with inappropriate driving pressures.

Fundamental to the respiratory transition at birth is the need to apply sufficient hydrostatic driving pressure to move lung liquid from airways and alveoli into the interstitium, thus allowing alveolar aeration and establishment of FRC before tidal ventilation (3). Because of the long time constants of the fluid-filled fetal lung, and the knowledge that volume change in the lung is determined by the product of pressure and time, an SI has been advocated as a potential method of optimizing lung aeration (3,4,23). However, both animal (1,6,14,17, 24–28) and human (7–13) studies have shown conflicting results, often inconsistent with the predicted mechanism of action of an SI (5). A commonality of these studies was the

use of pre-determined, and fixed, SI durations. This seems incongruous with the current focus on lung protection, as it does not account for the highly variable mechanical conditions of the diseased infant lung (29–32). Increasingly, clinicians are using individualized ventilation strategies, such as open-lung ventilation and volume-targeting, in an effort to avoid harmful lung volume states and achieve regional homogeneity (7,32). Previous work from our group, limited to a single GA, demonstrated great heterogeneity in the time constants of the respiratory system at birth, which influenced SI aeration outcomes (2,14,16). We have now demonstrated that GA independently influences aeration during an SI.

Preterm infants from as early as 23 weeks of gestation are now routinely actively resuscitated, and they are most likely to benefit from lung protective resuscitation. Prematurity represents the most frequent need for respiratory support at birth. There is increasing awareness that lung injury may

Figure 6. Summary of the relationship between GA and the volumetric behavior of the lung (ΔV_L) during an SI as the first inflation at birth for the 118-d (dashed dark gray line), 123-d (dashed black line), 127-d (dot/dash dark gray line), 132-d (dot/dash black line), and 139-d (black line) GA cohorts. ΔV_L represents the mean change for that cohort expressed as normalized change from preaeration (0%) and ΔV_L at the end of SI (100%; maximum volume). Gray dotted lines illustrate ΔV_L at 30, 60, and 90 s (x axis) and by time constant (τ) at 63.5% (τ), 86.5% (2τ), 95% (4τ), and 99% (5τ) of maximum ΔV_L (y axis). The more preterm groups achieved stable ΔV_L later, with the 118-d cohort achieving 50% of 139-d cohort ΔV_L at 30 s. GA, gestational age; SI, sustained lung inflation.

begin from the first inflation (33), focusing attention on lung-protective strategies in the delivery room. The last 20 weeks of gestation are associated with significant changes in fetal lung size, alveolar morphology, and surfactant function, along with increasing central drive and chest wall maturity (15,34). The finding in our current study that immature gestation was associated with longer respiratory time constants was fully expected. This, along with the histological and mechanical data following the SI, demonstrates that our GA cohorts were sufficiently different and representative of the spectrum of preterm infants in the NICU (35). The majority of lamb studies have used SI durations ≤ 60 s (refs 1,6,14,17,24–28). Only the term lambs in our study population had achieved stable aeration (five time constants) within 60 s, at the inflating pressure we used. By contrast, 60 s approximated only one time constant for the 118-d and 123-d groups. The lamb has similar fetal lung development as humans but different chest wall characteristics, and more lung liquid (19). Thus, in absolute terms, the T_{stable} durations we report are likely to be longer than those needed in human infants. Notwithstanding this, the relative magnitude of the differences in time constants at birth we observed would translate to significant SI duration requirements in humans, more so than currently accounted for in existing clinical trials.

The preterm lung has smaller total lung capacity than the term lung, a finding of our study, and larger relative deadspace because of reduced alveolar volume (15). A corollary of this is that targeting a delivered volume during an SI using airway opening volume, as previously advocated (26), is unlikely to achieve uniform aeration across gestations. Such an approach may result in injurious volume states if the delivered volume is too small or large for the recipient's lung.

Unlike respiratory support in the already aerated infant, child, or adult lung, the mechanical state of the lung and total lung capacity at birth is not known. This highlights the need to target the relative volumetric change rather than an absolute value. Direct feedback of the aeration process will be needed if preterm respiratory failure is to be supported with the same sophistication as in the NICU. Of the current delivery room assessment tools, only expired CO_2 allows such an approach (36), but is ETT leak-dependent. The latter is important, as unlike our study most infants are managed at birth with a facemask. Using current anatomically correct image reconstruction EIT algorithms offers direct visualization of aeration and ventilation independent of ETT leak, at least within the examined chest section (37). Although adult and pediatric EIT devices are available for use in the clinical setting, EIT use in neonates is currently limited to research (37). The development of rapid application electrode belts and instantaneously available online analysis during examination (37,38), as used in our study, offers future potential in the delivery room to guide both pressure and duration of SI and other respiratory strategies.

The use of EIT-guided SI delivery via a cuffed ETT resulted in homogeneous distribution of aeration between the gravity-dependent and nondependent regions of the lung, indicating similar regional time constants. This differs from studies of preterm infants in the NICU (27) and adults with surfactant-deficient acute respiratory failure (39), which are diseases characterized by gravity-dependent differences secondary to reduced C_{dyn} . The larger contribution of resistance in the fluid-filled fetal lung would explain our differences. Regional aeration volumes were similar to the anatomical potential, suggesting sufficient SI durations to achieve homogeneous aeration. The aeration heterogeneity noted in the 139-d cohort, with nondependent lung overdistension, is likely a consequence of excessive SI duration. This also illustrates the need to monitor the pattern of the time–volume relationship, as rapid change may generate injurious shear forces. Despite different resultant volumes, the time–volume relationship was similar across gestations, and predictable using a simple exponential model. This offers the potential for integration into resuscitation monitors and algorithms.

In our lambs, unlike human infants, spontaneous breathing was suppressed and the SI was delivered via a cuffed ETT to ensure reliable driving pressure delivery and mechanical evaluation. Most human infants have some spontaneous effort, or conversely irregular glottis function, which may alter aeration patterns and the reliability of the modeling. We contend that the influence of development on the mechanical properties of the lung applies irrespective of central respiratory drive and clinical care. The SI inflating pressure and subsequent positive end-expiratory pressure settings were based on values known to optimize outcomes in preterm lambs. It is possible that these values were not optimal for the more mature gestations evaluated (17,40). Despite being larger than most preterm lamb studies, our sample size of 9–11 per group may not have been sufficient to account for

within-group variability, especially as the ratio of male infants was not constant (although not statistically different) (16). This suggests that future physiological and interventional human studies of aeration at birth will need large sample sizes.

CONCLUSIONS

In our preterm lamb study, GA exerted a significant, and linear, influence on the volumetric behavior of the lung during an SI, delivered as the first inflation at birth. Longer SI durations were needed to achieve optimal aeration in the most preterm lambs. Clinical strategies at birth that use similar predetermined SI durations across broad gestations are likely to be too simplistic, and may inadvertently generate injurious volume states in some individuals. The highly predictable exponential time–volume behavior of the lung during the first inflation, irrespective of gestation, offers potential for mechanically appropriate individualized SI strategies to be developed.

AUTHOR CONTRIBUTIONS

K.E.McC., D.G.T., R.D., P.A.D., and P.G.D. developed the concept, designed the experiment, interpreted the data, and wrote the manuscript. K.E.McC. wrote the first draft. P.P., R.O., M.M., E.J.P., M.S., A.R., and A.T. were involved in all lamb experimental work. A.W. and A.A. designed the EIT image reconstruction algorithms. K.E.McC., A.T., and A.W. performed the data analysis. K.E.McC., D.G.T., A.A., M.M., and I.F. interpreted the EIT data. R.D. and E.Z. performed the forced-oscillation technique analysis. All authors contributed to redrafting the manuscript.

STATEMENT OF FINANCIAL SUPPORT

This study is supported by a National Health and Medical Research Council Project Grant, Canberra, Australia (Grant ID 1009287) and the Victorian Government Operational Infrastructure Support Program (Melbourne, Australia). D.G.T. is supported by a National Health and Medical Research Council Clinical Career Development Fellowship (Grant ID 1053889).

Disclosure: S.B. and A.W. are employees of Swisstom AG, a company producing commercial adult EIT and research devices. Swisstom customized the EIT hardware and software for the preterm lamb model used in this report using open-source software designed by A.A. Both helped interpret the EIT data and revised the manuscript. All EIT hardware and software used in this study were purchased at commercial rates by the Murdoch Childrens Research Institute without restrictions or obligations. The remaining authors declare no conflict of interest.
