## Abstract

Spinocerebellar ataxia 37 (SCA37) is caused by an (ATTTC)<sub>n</sub> insertion in a polymorphic ATTTT repeat in the non-coding region of *DABI*. The non-pathogenic alleles have a configuration [(ATTTT)<sub>7–400</sub>], whereas pathogenic alleles have a complex structure of [(ATTTT)<sub>60–79</sub>(ATTTC)<sub>31–75</sub>(ATTTT)<sub>58–90</sub>]. Molecular diagnosis of SCA37 is laborious because about 7% of the pentanucleotide repeat alleles in *DABI* are larger than 30 units and, thus, fail to amplify with standard PCR conditions, resulting in apparently homoallelism or in complete lack of PCR amplification in several cases. The molecular test currently available requires long-range PCR and sequencing analysis for the detection and characterization of these large alleles. We developed a simple assay capable of rapidly detecting the presence or absence of large pentanucleotide repeat sizes. This assay is based on repeat-primed PCR followed by high-throughput capillary electrophoresis. Combining the standard PCR with RP-PCR allows completion of the diagnosis in more than 80% of individuals, minimizing the number of samples that require long-range PCR followed by Sanger sequencing analysis. This assay meets many of the requirements for pre-screening of large cohorts of affected individuals.

## Introduction

A large number of neurological and neuromuscular diseases are caused by unstable repetitive tracts in coding or non-coding gene regions [1–3]. These include the expansion of trinucleotide repeats in coding regions, the most common being CAG repeats that encode toxic polyglutamine proteins [4, 5]. Tri-, tetra-, penta-, and hexanucleotide repeats in non-coding gene regions, however, are also responsible for many of these disorders [6–11]. In two of

the unstable repeat diseases, spinocerebellar ataxia type 31 (SCA31) and SCA37, there is a pentanucleotide repeat insertion in another polymorphic pentanucleotide repeat, which is a challenge for routine diagnostic testing [12, 13]. This is further complicated by the existence of very large non-pathogenic alleles comprised of pentanucleotide repeats [13, 14].

In SCA37, there is an (ATTTC)<sub>n</sub> insertion in the middle of a polymorphic ATTTT repeat in the 5'UTR region of *DABI* (*DAB1*, reelin adaptor protein) [13]. The non-pathogenic alleles have ATTTT repeats that can vary from 7 to 400 units and never contain ATTTC. Standard PCR amplification of the pentanucleotide repeat in *DABI* can easily detect alleles shorter than 30 units [13]; however, amplification of larger alleles is technically challenging and requires long-range PCR [13]. By standard PCR, finding only one band of potentially two normal alleles of the same size (homoallelism) is not conclusive because there is the possibility of preferential amplification of the shorter allele in the presence of a large allele that is not amplified. As the molecular diagnosis relies on the presence of the ATTTC insertion and since 7% of non-pathological alleles are larger than 30 ATTTTs [13], long-range PCR and sequencing analysis are frequently required.

To facilitate screening of large cohorts of patients with SCA, there is a need for simple and inexpensive tests with high sensitivity and specificity. Expanded alleles in several of the SCAs and in fragile-X syndrome can be detected using a fluorescent repeat-primed PCR assay [15, 16]. In SCA37, the (ATTTC)<sub>n</sub> insertion has been successfully detected by a similar repeat-primed PCR adapted to the specificity of the pentanucleotide repeat insertion [13]. DNA samples with detected ATTTC repeat insertions are, then, amplified by long-range PCR followed by sequencing analysis of the products obtained. This method is adequate for repeat insertions flanked by ATTTT stretches of ~100 units; however, for much larger ATTTT flanking repeats the ladder of peaks obtained would fall out of the electropherogram detection.

For screening purposes, this limitation of the ATTTC RP-PCR negatively affects the sensitivity of the test. To overcome this problem, we have developed an ATTTT RP-PCR that allows detection of pentanucleotide repeat alleles in *DABI* larger than 30 units. With this screening method both normal alleles larger than 30 ATTTTs and alleles with the ATTTC repeat insertion flanked by ATTTTs are detected. The final step is always sequencing analysis of the products of long-range PCR to identify alleles with the ATTTC repeat insertion.

## Subjects and methods

### DNA samples from affected individuals and controls

This study used the de-identified, previously collected, DNA samples of affected individuals with SCA37 as well as anonymized DNA samples from control individuals; they were described in a previous study [13].

### Repeat-primed PCR for the ATTTT repeat

The pentanucleotide repeat sequence in *DABI* was amplified by ATTTT RP-PCR with primers 24F (6-FAM-5'-GAAG TGGTCCTCCCAAGTCA-3'), FLAG (5'-TACGCATCC CAGTTTGAGACG-3'), and RP-AATAA (5'-TACGCATC CCAGTTTGAGACGAATAAAAATAAAAATAAAA ATAA-3'). The forward primer (24F) was a locus-specific primer, while the RP-AATAA primer was an ATTTT-repeat specific. The RP-AATAA primer had a DNA tail sequence at the 5' end (absent in the human genome) and the reverse primer FLAG had the 5' tail sequence of the RP-AATAA primer. PCR was performed with 100 ng genomic DNA, 1× HotStarTaq Master Mix (Qiagen), 0.8 μM primer 24F and primer FLAG, and 0.4 μM primer RP-AATAA, in 12.5 μL. The initial RP-PCR step was at 95 °C for 15 min and was followed by 40 cycles (94 °C for 1 min,

54 °C for 1 min, and 72 °C for 2 min and 30 s) and a final extension of 10 min at 72 °C. RP-PCR products were detected by capillary electrophoresis of 3 μL of RP-PCR product mixed with 0.5 μL of GS500(-250)LIZ size standard in Hi-Di™ formamide (Applied Biosystems). Samples were denatured at 95 °C, for 5 min, before loading onto an ABI3730xl DNA Analyzer on a 36-cm capillary. Fragment sizes were analyzed with GeneMapper v.4.0 (Applied Biosystems).

### Sequencing analysis

The long-range PCR [13] was performed in duplicate for each sample with positive detection by ATTTT RP-PCR; PCR products were separated by electrophoresis in a 1% agarose gel. For each sample, each DNA and corresponding duplicate band (of 0.9 kb or larger) were sliced from the gel and the DNA was extracted together using the QIAquick gel extraction kit (Qiagen) following the manufacturer instructions. The DNA was analyzed by Sanger sequencing. Sequencing analysis in the forward orientation used 2 μL of DNA extracted from the duplicate bands together, 4 μL of BigDye terminator v.1.1 (Applied Biosystems), 0.5× BigDye sequencing buffer, 2.5 μM of primer 24F (5'-GAAGTGGTCCTCCCAAGTCA-3') in a final volume of 20 μL. Sequencing analysis in the reverse orientation used 2 μL of DNA, 8 μL of BigDye terminator v.1.1, 0.5× BigDye sequencing buffer and 1.5 μM of primer 24R4 (5'-GAGACCAGCCTGGGCAAC-3') in a final volume of 20 μL. Sequencing reactions were performed, for both forward and reverse orientations, with an initial denaturation of 5 min at 95 °C followed by 50 cycles of 30 s at 95 °C, 10 s at 56 °C, and 4 min at 60 °C and a final extension of 10 min at 60 °C.

## Results

### RP-PCR of pentanucleotide repeat alleles

Standard PCR analysis of the pentanucleotide repeat in *DABI* resulted in the amplification of two, one or no alleles in samples from affected or control individuals (Table 1); this method could not amplify successfully alleles larger than 30 repeats [13]. To detect pentanucleotide repeats larger than 30 units in *DABI* for the screening of SCA37 in large cohorts of individuals, we developed a simple ATTTT RP-PCR (Fig. 1). After capillary electrophoresis and electropherogram analysis, we observed that alleles larger than 30 repeats produced a ladder of multiple peaks 5-bp apart and extending beyond the 250 bp, while this ladder ended below 250 bp for alleles smaller than 30 repeats. Thus, we predefined a cut-off value of 250 bp below which the test was

**Fig. 1** ATTTT RP-PCR to detect large pentanucleotide alleles in *DAB1*. **a** Schematic representation of the ATTTT RP-PCR primers that anneal with the repetitive ATTTT region, resulting in DNA amplification in normal and mutant alleles. **b** Electropherograms showing the fluorescent ATTTT RP-PCR analysis in control individuals from Table 1: C-75, C-88, C-91, C-95, and C-44; and in SCA37 affected individuals A-1 and A-9

**Fig. 3** Workflow for  $(ATTTC)_n$  insertion screening. This workflow decreases the number of samples that require long-range PCR followed by Sanger sequencing. First, it is performed a standard PCR, followed by  $ATTTT$  RP-PCR in samples wherein only one allele is amplified. The  $ATTTT$  RP-PCR distinguishes homoallelism from large allele carriers. In samples with a positive result for the  $ATTTT$  RP-PCR long-range PCR and Sanger sequencing are performed to assess the size and composition of large alleles. In the control population studied, 71% of the samples required only standard PCR to complete the negative diagnosis; standard PCR followed by  $ATTTT$  RP-PCR in samples with one allele provided a conclusive negative result in 82% of the total samples; the remaining 18% required long-range PCR followed by Sanger sequencing

detection of both alleles (Fig. 3). Larger alleles, however, are not successfully amplified by standard PCR conditions. Therefore, in samples with apparent homoallelism  $ATTTT$  RP-PCR proves advantageous by enabling a conclusive negative result in a total of 82% of the samples. On the other hand, this method allows detection of pathogenic alleles with the configuration  $[(ATTTT)_{60-79}(ATTTC)_{31-75}(ATTTT)_{58-90}]$  despite the possibility of missing alleles with very different configurations. Samples with a positive  $ATTTT$  RP-PCR need to be amplified by long-range PCR followed by sequencing analysis.

In conclusion, we suggest that the  $ATTTT$  RP-PCR can be used as a rapid screening test in the diagnostic protocol of SCA37 provided this is always followed by long-range PCR amplification and sequencing analysis if a positive  $ATTTT$  RP-PCR is detected.
