Mice deficient in the IL-10 pathway are the most widely used models of intestinal immunopathology. IL-17A is strongly implicated in gut disease in mice and humans, but conflicting evidence has drawn IL-17's role in the gut into question. IL-22 regulates antimicrobial and repair activities of intestinal epithelial cells (IECs) and is closely associated with IL-17A responses but its role in chronic disease is uncertain. We report that IL-22, like IL-17A, is aberrantly expressed in colitic *Il10*^{-/-} mice. While IL-22⁺ Th17 cells were elevated in the colon, IL-22-producing ILC3s were highly enriched in the small intestines of *Il10*^{-/-} mice. Remarkably, *Il10*^{-/-}*Il22*^{-/-} mice did not develop colitis despite retaining high levels of Th17 cells and remaining colonized with colitogenic *Helicobacter* spp. Accordant with IL-22-induced IEC proliferation, the epithelia hyperplasia observed in *Il10*^{-/-} animals was reversed in *Il10*^{-/-}*Il22*^{-/-} mice. Also, the high levels of antimicrobial IL-22-target genes, including *Reg3g*, were normalized in *Il10*^{-/-}*Il22*^{-/-} mice. Consistent with a heightened antimicrobial environment, *Il10*^{-/-} mice had reduced diversity of the fecal microbiome that was reestablished in *Il10*^{-/-}*Il22*^{-/-} animals. These data suggest that spontaneous colitis in *Il10*^{-/-} mice is driven by IL-22 and implicates an underappreciated IL-10/IL-22 axis in regulating intestinal homeostasis.

Mucosal Immunology (2020) 13:493–506; <https://doi.org/10.1038/s41385-019-0252-3>

INTRODUCTION

Based on cues from the microenvironment, the mucosal immune system fine-tunes immune effector programs to maximize host defenses at barrier surfaces while preventing excess inflammation to avoid damage to host tissues. In the gut, dysregulation of this dynamic process can result in chronic inflammation and disease pathology. The etiology of inflammatory bowel disease (IBD), which encompasses Crohn's disease and colitis, is still poorly understood despite being intensively studied. Our understanding of the immune and microbial factors that contribute to disease susceptibility have been complicated, at least in part, by difficulties in interpreting data generated under different experimental conditions, and with different animal models of IBD.^{1,2}

IL-10 is an immunoregulatory cytokine that plays a central role in regulating intestinal inflammation in humans and mice.³ Mice deficient in IL-10⁴ or the IL-10 receptor⁵ develop spontaneous colitis early in life and are one of the most widely used animal models for studying the pathogenesis of human IBD.^{6,7} The development of colitis in IL-10-deficient mice is dependent on the intestinal microbiota.⁸ More specifically, co-colonization with "pathobionts" such as *Helicobacter* spp., which do not cause disease in immunocompetent mice,⁹ are required for the development of colitis in *Il10*^{-/-} mice. Although it is clear that excessive immune reactivity to microbial antigens triggers colitis in *Il10*^{-/-} mice,^{10,11} remarkably, the host factors which drive intestinal pathology have been difficult to define.

Early work suggested that dysregulation of Th1 immunity (IL-12/IFN- γ) was responsible for colitis in *Il10*^{-/-} mice.¹² Prior to the

discovery of the Th17 pathway (IL-23/IL-17), early work naturally focused on Th1-mediated responses (IL-12/IFN- γ). An important study by Yen and colleagues in 2006, specifically examined the contributions of IL-12-dependent Th1 and IL-23-dependent Th17 immunity to the development of colitis.¹³ They demonstrated that co-deletion of IL-23 (*Il10*^{-/-}*Il23p19*^{-/-}) but not IL-12 (*Il10*^{-/-}*Il12p35*^{-/-}), rescued *Il10*-deficient mice from spontaneous colitis.¹³ This study offered convincing evidence that excessive production of IL-17, driven by IL-23, was in fact primarily responsible for the development of colitis in *Il10*^{-/-} animals.¹³ Thus, the prevailing model suggests that excessive Th17 development, driven by IL-23, is responsible for IBD pathology.

Additional studies have largely supported IL-23's role in promoting intestinal inflammation,^{14–16} however, IL-17's role has been somewhat less clear. A group of reports have accumulated suggesting that intestinal inflammation occurs independently of IL-17 and can be worsened when IL-17 is inhibited.^{15,17–19} These data are consistent with the disappointing results from clinical trials using IL-17A-blocking or IL-17RA-blocking antibodies to treat IBD. In these trials, Crohn's disease patients receiving anti-IL-17A or -IL-17RA therapy had no clinical improvement and disease symptoms were exacerbated in some recipients.^{20,21} These data highlight the need to reexamine existing models based on IL-17-mediated gut pathology and to reconsider other factors that may drive disease susceptibility.

IL-22 is closely associated with Th17 immunity, despite being a member of the IL-10 family, due to its complementary functions and overlapping expression with IL-17A.²² Although frequently

co-expressed with IL-17A, IL-22-producing cells are far less abundant,²³ which together confounds efforts to identify the individual contributions of IL-22 and IL-17 to host defense and disease pathogenesis.^{16,24} Th17, Th22, and ILC3s are the primary sources of IL-22 in the gut and the cellular source of IL-22 appears to play an important part in determining its biological actions.^{23,25} Recent evidence suggests that different IL-22-secreting subsets emerge during the course of immune responses depending on the nature of the insult²⁶ and may be selectively distributed in different anatomical locations within the GI tract.²⁷ However, the factors that regulate IL-22 expression by these different cell types and mediate IL-22's protective or pathogenic activities remain poorly understood.

Although it is clear that IL-10 and IL-22 contribute distinctly to intestinal health, it remains uncertain if or how the IL-10 and IL-22 pathways interconnect and to what extent, if any, that IL-22 contributes to pathogenesis in IL-10-deficient disease models. In this study, we provide compelling evidence indicating that IL-10 and IL-22 form a functional network which counterbalances antimicrobial and tissue repair defenses and anti-inflammatory responses to maintain both immune microbial homeostasis in the gut. We determined that IL-22-expressing ILC3s selectively accumulate in the small bowel of *Il10*^{-/-} mice and IL-10/IL-22 double-deficient mice (*Il10*^{-/-}*Il22*^{-/-}) do not develop colitis despite remaining colonized with colitogenic *Helicobacter* spp. and retaining high frequencies of Th17 cells in colonic tissues. Our data indicate that IL-22 is necessary for the development of spontaneous colitis in *Il10*^{-/-} mice while excessive IL-17A is not sufficient to induce disease. Taken together, these data challenge current models of chronic intestinal inflammation and suggest that IL-10 and IL-22 form a regulatory axis, which balances antimicrobial immunity and immune homeostasis.

RESULTS

IL-22 is overexpressed in *Il10*^{-/-} mice

Helicobacter-colonized *Il10*^{-/-} mice develop spontaneous colitis early in life.^{4,8,9} The progressive disease pathology is characterized by excessive epithelial hyperplasia, microbial dysbiosis, and the accumulation of infiltrates in colonic tissues, including large numbers of Th17 cells that are thought to mediate immunopathology.^{11,13,28,29} Though IL-22 is largely thought to be protective in the gut, it has also been linked to disease pathology.^{30,31} Nevertheless, IL-22's potential role in the development of colitis in *Il10*^{-/-} mice has not been carefully studied. Given the growing uncertainties about IL-17's role in IBD, we began to explore IL-22's potential role in the development of colitis in *Il10*^{-/-} mice. Analysis of IL-22 mRNA expression in different regions of the colon as well as the small intestine (SI) and spleen indicated that IL-22 transcript levels were significantly elevated in all of the tissues tested from colitic *Il10*^{-/-} compared to age-matched WT mice (Fig. 1a). Likewise, *Il10*^{-/-} mice had significantly higher levels of IL-22 protein in tissue culture explants from the colon and SI (Fig. 1b). Interestingly, for both strains, the highest levels of IL-22 mRNA and protein were observed in the SI (Fig. 1a, b).

To determine the cellular source(s) of IL-22 and patterns of IL-22 and IL-17A co-expression in mucosal and secondary lymphoid tissues of healthy WT and colitic *Il10*^{-/-} mice, we performed flow cytometry analysis. First, we focused on characterizing IL-22 production in CD4⁺ T cells. In addition to the total percentage of CD4 T cells producing IL-22, we also examined IL-22-producing T cell subsets defined as IL-22⁺ IL-17A⁻ single positive (SP) (i.e. Th22) and IL-22⁺ IL-17A⁺ double positive (DP) (i.e. Th17) as these subsets have been reported to be primary sources of IL-22 in the colon, mesenteric lymph nodes (MLN), and spleen during inflammatory challenge.^{32,33} It is important to note that although the absolute numbers of cells isolated were invariably higher in

Il10^{-/-} compared to WT mice in all tissues tested, on average from 2 to 5 fold (data not shown), a relatively high degree inter-experiment variation in cell recovery from some tissues precluded a comprehensive flow cytometric analysis based on absolute cell numbers. Nonetheless, the relative percentages of the leukocyte subsets examined were quite consistent within groups and between experiments. In agreement with the mRNA and explant data (Fig. 1a, b), the highest percentages of IL-22-producing T cells were in the small intestine, specifically in the sLPL fraction, of both WT and *Il10*^{-/-} mice (Fig. 1c, d). While we consistently observed higher levels of total IL-22-producing CD4⁺ T cells (IL-22 SP + IL-22/IL-17A DP) in tissues from *Il10*^{-/-} compared to WT mice, only the spleen and colonic intraepithelial lymphocytes (cIEL) reached statistical significance (Fig. 1d). The majority of IL-22-producing T cells from *Il10*^{-/-} mice trended towards IL-17A co-expression in all tissues examined and were significantly higher in the spleen and cIEL compared to WT mice. This was also the case in the cLPL and sLPL fractions despite the fact that the total levels of IL-22-producing T cells were not significantly different between WT and *Il10*^{-/-} mice (Fig. 1d). Interestingly, compared to *Il10*^{-/-} mice, intestinal T cell-derived IL-22 in WT animals trended towards higher proportions of Th22 cells and was significantly higher in sLPLs.

Our data indicated that in tissues examined, the vast majority of IL-22⁺ cells in both WT and *Il10*^{-/-} mice, were CD3⁺CD4⁺ Th17 and Th22 cells. However, we noted an exception exclusively in sLPLs from *Il10*^{-/-} mice in which a sizeable population of IL-22⁺ CD45⁺CD3⁻ lymphocytes were identified which secreted little IL-17A (Fig. 1e). Though usually found only in low abundance, we suspected that these cells could be ILC3s. ILC3s consist of at least two subpopulations in mice but their high degree of heterogeneity and plasticity has hindered efforts to classify ILC3 subsets phenotypically and functionally.²⁷ Nevertheless, ILC3s are unified by RORγt expression and the preferential production of IL-22 and/or IL-17A.³⁴ We examined the total levels of ILC3s (defined as CD45⁺CD3⁻RORγt⁺IL-7Rα⁺³⁵ and refer to the gating strategy in Supplementary Fig. 1) in mucosal and secondary lymphoid tissues from WT and colitic *Il10*^{-/-} mice. Although *Il10*^{-/-} mice had higher total numbers of leukocytes, including CD3⁻ lymphocytes in all tissues tested compared to WT (data not shown and Supplementary Fig. 1), the relative percentages of ILC3s were comparable in most tissues (Fig. 1f). As expected, a substantial population of ILC3s was observed specifically in sLPLs from *Il10*^{-/-} mice (Fig. 1f). Interestingly, significantly higher levels of ILC3s were observed in spleens of WT compared to *Il10*^{-/-} mice (Fig. 1f). We verified that a large fraction of the amassed ILC3s in *Il10*^{-/-} sLPLs expressed only IL-22 (IL-22 SP) with only a small subset expressing IL-17A (Fig. 1g, h). As mentioned, ILC3s can be subdivided into smaller subsets based largely on the surface expression of NKp46 and CCR6 +/− CD4.²⁷ We found that the majority of total ILC3s as well as IL-22⁺ ILC3s in the sLPL of *Il10*^{-/-} mice did not express NKp46 or CCR6, though the percentages of NKp46⁺ and CCR6⁺ ILC3s (total ILC3s) tended to be higher in *Il10*^{-/-} compared to WT mice (Supplementary Fig. 1 and data not shown).

To determine if the elevated levels of IL-22-expressing cells and mRNA in *Il10*^{-/-} mice were restricted to tissues, we examined IL-22 levels in the serum. While IL-22 was readily detectable in the serum of *Il10*^{-/-} mice, no IL-22 was detected in the serum of matched WT animals (Fig. 1i). These data indicate that IL-22 is over-expressed both within mucosal tissues and the periphery and ILC3s accumulating in the small bowel are the primary source of IL-22 in *Il10*^{-/-} mice.

IL-22-deficiency prevents spontaneous colitis in *Il10*^{-/-} mice
To determine the role of IL-22 in the development of spontaneous colitis, we crossed susceptible *Il10*^{-/-} mice (colonized with *Helicobacter typhlonius*), with disease-free *Il22*^{-/-} mice harboring both *H. typhlonius* and *H. mastomyrinus*. We have

previously shown that *H. typhlonius* is associated with development of colitis in *Il10*^{-/-} animals.²⁸ Studies from other groups have demonstrated *H. mastomyrinus* to be even more pathogenic than *H. typhlonius*.³⁶ We confirmed that while fully backcrossed *Il10*^{-/-}*Il22*^{-/-} mice harbored both *Helicobacter* spp. (data not

shown), *Il10*^{-/-}*Il22*^{-/-} mice did not develop chronic colitis (Fig. 2).

The development of colitis in *Il10*^{-/-} mice colonized with *Helicobacter* spp. is highly correlated with rectal prolapse.³⁷ We found that by 3 months of age, about 20% of *Il10*^{-/-} mice had

Statistical analyses (* $p < 0.05$, ** $p < 0.01$ using the Mann-Whitney *U* test—error bars represent SD).

developed rectal prolapse and this number increased to 80% by 6 months of age. In contrast, but similar to WT animals, *Il10*^{-/-}*Il22*^{-/-} mice did not develop rectal prolapse (Fig. 2a). A subset of *Il10*^{-/-}*Il22*^{-/-} mice was observed for a period of more than 1.5 years during which they remained healthy and free of disease (data not shown). Macroscopically, *Il10*^{-/-} mice exhibited thickening of the colonic wall, shortened colonic length, intussusception of the cecum and enlarged mesenteric lymph nodes (MLN) and spleens (Fig. 2b). Surprisingly, *Il10*^{-/-}*Il22*^{-/-} as well as *Il22*^{-/-} exhibited significantly longer colon lengths than both WT and *Il10*^{-/-} mice (Fig. 2b, c). The colonic thickening, cecal intussusception, and splenic enlargement observed in *Il10*^{-/-} mice was completely abrogated in *Il10*^{-/-}*Il22*^{-/-} mice. However, similar to *Il10*^{-/-} mice, double-deficient mice had enlarged mesenteric lymph nodes compared to WT and *Il22*^{-/-} mice (Fig. 2b).

Compared to WT controls, colons from *Il10*^{-/-} mice had marked mucosal hyperplasia and thickening (Fig. 2d), increased cellular infiltrates, erosion, and ulceration of the epithelium, and crypt abscesses as reported previously in *Il10*^{-/-} mice.^{4,28} Histology scores for colitis using the Jackson Laboratory (TJL) system reflected these findings and indicated that *Il10*^{-/-}*Il22*^{-/-} mice were protected from colitis (Fig. 2e). Lipocalin (Lcn-2) is strongly associated with intestinal inflammation^{38,39} and as expected, the high levels of fecal Lcn-2 in *Il10*^{-/-} mice were significantly reduced in *Il10*^{-/-}*Il22*^{-/-} mice (Fig. 2f). Interestingly, the levels of Lcn-2 in *Il10*^{-/-}*Il22*^{-/-} mice were still significantly higher compared to fecal samples from both WT and *Il22*^{-/-} mice. These data are in line with a recent report indicating that IL-17A and ILC3-derived IL-22 synergistically induce Lcn-2 expression from IECs⁴⁰ and suggest that IL-17A levels remain high in disease-free *Il10*^{-/-}*Il22*^{-/-} mice. Taken together, these data indicate that IL-22 is necessary for the development of chronic colitis and plays a central, pathogenic role in the gut in the context of *Il10*-deficiency.

Overall, *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice have similar distributions of leukocyte subsets with some tissue-specific exceptions. To characterize cell populations associated with absence of disease in *Il10*^{-/-}*Il22*^{-/-} mice we examined leukocyte distributions in the various mouse strains. As mentioned, *Il10*^{-/-} mice have high numbers of leukocytes infiltrating secondary lymphoid and intestinal tissues,^{4,28} and consistent with previous reports,¹² we observed higher frequencies of CD4⁺ T cells in the cIEL and cLPL fractions compared to WT mice. Surprisingly, we also found higher frequencies of CD4⁺ T cells in the colons of *Il10*^{-/-}*Il22*^{-/-} mice compared to WT (Fig. 3a). No differences in the percentages of CD8⁺ cytotoxic T cells, CD3⁺CD19⁺ B cells or CD11b⁺Ly6C⁺Ly6G⁺F4/80⁺ side scatter low (SSC^{lo}) macrophages were observed between the groups (Fig. 3b–d respectively). However,

higher frequencies of CD11b⁺Ly6C⁺Ly6G⁺F4/80⁺ neutrophils in the spleens of *Il10*^{-/-} mice, whereas the percentages of neutrophils from *Il10*^{-/-}*Il22*^{-/-} animals were comparable to levels observed in WT and *Il22*^{-/-} spleens (Fig. 3e). Interestingly, the percentage of neutrophils was also elevated in the cIEL and cLPL fractions of both *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice compared to WT animals (Fig. 3e). Of note, the numbers and percentages of leukocyte subsets were comparable between WT and *Il22*^{-/-} mice for all of the tissues examined (Fig. 3).

The tissue-specific disparity in neutrophil frequencies prompted us to examine the distribution of leukocyte subsets in the periphery (Fig. S2). Although *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice trended towards higher numbers of leukocytes in the blood (Fig. S2A), no significant differences between the groups were observed for white blood counts (WBC) or lymphocytes (Fig. S2B). However, in agreement with findings in the spleen, complete blood counts (CBCs) revealed elevated numbers of neutrophils in the peripheral blood of *Il10*^{-/-} mice compared to *Il10*^{-/-}*Il22*^{-/-} as well as WT and *Il22*^{-/-} animals (Fig. S2C). In addition, *Il10*^{-/-} mice harbored higher numbers of monocytes whereas *Il10*^{-/-}*Il22*^{-/-} mice had numbers comparable to WT (Fig. S1D). Similar to WBC, platelet counts trended higher in *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice but did not reach statistical significance (Fig. S2E). Thus, overall, *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice have higher levels of leukocytes in intestinal tissues and a selective enrichment of Th cells and neutrophils in the colon.

Il10^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice have higher frequencies of Th17 cells in tissues

Dysregulation of Th1 and/or Th17 responses has been associated with intestinal inflammation.^{12,28,41,42} In *Il10*^{-/-} mice, the excessive accumulation of Th17 cells in the gut is thought to mediate intestinal disease⁴³ and we found that the levels of CD4⁺ T cells remained high in colonic tissues of *Il10*^{-/-}*Il22*^{-/-} mice (Fig. 3a). Taken together with our finding that fecal Lcn-2 levels were reduced in *Il10*^{-/-}*Il22*^{-/-} compared to *Il10*^{-/-} mice but elevated compared to WT and *Il22*^{-/-} mice (Fig. 2f) suggested that Th17 cells may remain high in disease-free *Il10*^{-/-}*Il22*^{-/-} mice. Thus, we examined the frequencies of CD4⁺ Th17 and Th1 subsets in intestinal and secondary lymphoid tissues based on the expression of IFN- γ and IL-17A. Consistent with elevated frequencies of CD4⁺ T cells in colonic tissues (Fig. 3a), *Il10*^{-/-} mice had significantly higher percentages of IL-17A-expressing CD4⁺ Th17 cells in cIEL and cLPL fractions as expected, compared to WT and *Il22*^{-/-} mice (Fig. 4a). Remarkably, disease-free *Il10*^{-/-}*Il22*^{-/-} mice had similarly high levels of Th17 cells in colonic tissues. This suggests that IL-17A regulation is independent of IL-22. In addition, although we did not detect differences in the overall percentages of CD4⁺ T cells in other tissues (Fig. 3a), the levels Th17 cells in the spleen, MLN, and sLPL of

Fig. 2 IL-22 deficiency prevents the development of spontaneous colitis in *Il10*^{-/-} mice. **a** Prevalence of rectal prolapse ($n = >60$ per group) in WT, *Il10*^{-/-}, *Il22*^{-/-}, and *Il10*^{-/-}*Il22*^{-/-} mice. **b** Representative gross images of organs of the gastrointestinal tracts from each strain. **c** Colon length for each strain ($n = 11$ per group). **d** Representative photomicrographs of haematoxylin and eosin stained colons (x20). **e** Histological disease scores ($n = 8$ /group). **f** Fecal Lcn-2 levels ($n = 8$ /group). Statistical analyses (***) $p < 0.0001$ using the Mann-Whitney *U* test (error bars represent SEM).

both *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} were significantly elevated compared to WT (and *Il22*^{-/-}) mice. Interestingly, though the percentages of IFN- γ ⁺CD4⁺ Th1 cells tended to be higher in intestinal tissues of *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice, only the sIELs were significantly different (Fig. 4b). These data suggest that the well-known accumulation of Th17 cells in intestinal tissues of IL-10-deficient mice is not sufficient to induce colitis.

Il10/Il22 double-deficiency results in reduced fecal IgA and IgG. In addition to T cells, B cells and mucosal antibodies play important roles in maintaining immune-microbial homeostasis and barrier integrity in the gut.² Studies in *Il10*^{-/-} mice have shown that IgA and IgG1 levels are elevated in the serum⁴⁴ and serum IgG is reactive against enteric bacterial antigens.⁴⁵ To determine the impact of double-deficiency in IL-10 and IL-22 on the levels of mucosal antibody we measured immunoglobulin levels in the feces in our mouse strains. While the levels of both IgA and IgG were significantly elevated in feces from *Il10*^{-/-} mice compared to other strains, fecal antibody levels from *Il10*^{-/-}*Il22*^{-/-} mice were similar to those observed in WT (and *Il22*^{-/-}) mice (Fig. 5a, b). Although the antigenic specificities and subclass of fecal immunoglobulins have not been determined, these data suggest that an imbalance in the IL-10/IL-22 axis results in dysregulation of mucosal antibody responses.

Antimicrobial IL-22-target genes are upregulated in colonic tissues from *Il10*^{-/-} mice but are normalized in disease-free *Il10*^{-/-}*Il22*^{-/-} mice

To identify genes that may underlie protection from colitis in *Il10*^{-/-}*Il22*^{-/-} mice, we examined mRNA expression profiles in tissue samples from the distal colons of age-matched and sex-matched WT, *Il10*^{-/-}, *Il22*^{-/-}, and *Il10*^{-/-}*Il22*^{-/-} mice ($n = 4$ mice/group) using the TaqMan® OpenArray® Mouse Inflammation Panel. For relative mRNA expression analyses, each experimental group (strain) was compared to WT to identify differentially expressed genes. Significantly different genes were defined based on q -values smaller than 0.05 and fold change >2 . Of 632 genes examined, 121 and 111 genes were differentially expressed in the distal colons from *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice, respectively, compared to WT (Fig. 6a). The gene expression profile of *Il22*^{-/-} mice was remarkably similar to WT mice (Fig. 6b–d) and no significant differences were identified.

Genes differentially expressed in *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice were subdivided into three groups based on their patterns of expression compared to WT (Fig. 6a). Group 1 was comprised of genes differentially expressed in both *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice and likely represent genes affected by IL-10 independently of IL-22 (Fig. 6b; Supplementary Table 1). Like the similar distributions of inflammatory cells observed in *Il10*^{-/-} and

Data represent means from 4 to 5 individual experiments composed of cells obtained from 1 to 3 mice (male, between 8 and 12 weeks of age) per group (**p* < 0.05 using the Mann-Whitney *U* test (error bars represent SD)).

Il10^{-/-} *Il22*^{-/-} mice, there was a high degree of overlap in Group 1 genes (78 shared genes) (Fig. 6a). Group 1 genes included important mediators of inflammation, such as *Il17a*, *Cxcl1*, *Nos2*, *Il1b*, and *Cd4*, as well as molecules important in antigen presentation such as *Cd74* and *B2m* (Fig. 6b). Group 2 was comprised of genes differentially expressed only in *Il10*^{-/-} *Il22*^{-/-} mice compared to WT and likely represent genes affected by both IL-10 and IL-22 (Fig. 6c and Supplementary Table 2). Group 2 genes included *Fpr3*, *Cd40* and *Cd40L*, *Il18* and *Il18rap*.

Group 3 was comprised of genes differentially expressed only in *Il10*^{-/-} mice compared to WT (Fig. 6d and Supplementary Table 3) and are likely to represent, at least in part, genes that are affected by overexpression of IL-22. Indeed, in agreement with our initial observations (Fig. 1a, b) mRNA for *Il22* as well as several antimicrobial IL-22-target genes, such as *Reg3g* and *Muc1* were upregulated in *Il10*^{-/-} mice but not in *Il10*^{-/-} *Il22*^{-/-} mice. Results from these experiments were validated by separate real-time qPCR analysis for Group 3 genes, which included *Il22* (Fig. 6e), several IL-22-target genes (*Reg3g* (Fig. 6f), *s100a8* (Fig. 6g), *Muc1* (Fig. 6h)), and *Il21* (Fig. 6i), which is known to regulate both IL-10 and IL-22 expressions.⁴⁶ In addition, several genes that were not differentially expressed between the groups, including *Il23a*, *Il23ra*, and *Il22ra2*, were independently confirmed by RT-qPCR (data not shown). Taken together, these data indicate that IL-10 is a negative

regulator of IL-22 expression in the gut and in the absence of IL-10, aberrant IL-22 expression induces the overexpression of IL-22-target genes associated with antimicrobial immunity.

Microbial diversity is re-established in *Il10*^{-/-} *Il22*^{-/-} mice but with altered composition

IL-22 promotes intestinal health in part, by regulating the microbiota.⁴⁷ Chronic intestinal inflammation is associated with reduced microbial diversity in humans^{48,49} and *Il10*^{-/-} mice^{8,50} but the mechanism remains unclear. Our data indicate that IL-22-dependent antimicrobial genes are highly upregulated in *Il10*^{-/-} mice (Fig. 6). Thus, we explored the possibility that the IL-22 pathway drives microbial dysbiosis in *Il10*^{-/-} mice by sequencing and analyzing fecal 16s rRNA isolated from each mouse strain. The number and relative abundance of bacterial phylotypes in the gastrointestinal tract are often decreased during states of chronic inflammation.^{51,52} Accordingly, the Chao1 index (Fig. 7a) which measures the richness (total number) of phylotypes revealed that *Il10*^{-/-} mice trended lower in diversity compared to WT mice (*p* = 0.102, Supplementary Table 4). Lower diversity in *Il10*^{-/-} mice was also evident when compared to *Il10*^{-/-} *Il22*^{-/-} mice (*p* = 0.012) which indicates that loss of IL-22 significantly compensated for the negative impact of IL-10 deficiency on the number of phylotypes in the fecal microbiome. Interestingly, IL-22 deficiency

Fig. 5 Fecal IgG and IgA levels are normalized in *Il10*^{-/-}*Il22*^{-/-} mice. **a** Fecal IgA and **b** IgG levels in WT, *Il10*^{-/-}, *Il22*^{-/-}, and *Il10*^{-/-}*Il22*^{-/-} mice (male, 16–20 weeks of age, *n* = 10–12 mice per group) (***) *p* < 0.001, using the Mann–Whitney *U* test (error bars represent SEM)).

Fig. 6 Distal colon tissues from *Il10*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice have similar gene expression patterns but IL-22 target genes associated with antimicrobial responses are normalized to WT levels in *Il10*^{-/-}*Il22*^{-/-} mice. **a** Venn diagram from TaqMan OpenArray results depicting differential gene expression in distal colons of *Il10*^{-/-} and/or *Il10*^{-/-}*Il22*^{-/-} mice compared to WT mice (*n* = 4 mice per strain, 20 weeks of age) (*q* = 0.05, fold change boundary = 2). Heatmaps of **b** Group 1, **c** Group 2, and **d** Group 3 with select genes shown. Each line represents a single probe and each column a single mouse. Blue represents probes that were at least two-fold lower; red represents probes that were at least two-fold higher compared to WT mice. **e–i** Independent RT-PCR validation of mRNA expression for selected genes in the distal colons of WT, *Il10*^{-/-}, *Il22*^{-/-}, and *Il10*^{-/-}*Il22*^{-/-} mice (*n* = 4–7) (***) *p* < 0.001, ***p* < 0.01, **p* < 0.05, using 1-way ANOVA and Bonferroni post-test—error bars represent SEM).

Fig. 7 Reduced microbial diversity in *Il10*^{-/-} mice is restored to WT levels in *Il10*^{-/-}*Il22*^{-/-} mice albeit a markedly altered microbial signature. **a** Chao 1 index, **b** principal component analysis (unweighted, UniFrac analysis) based on 16S rRNA sequencing of DNA isolated from the feces of WT, *Il10*^{-/-}, *Il22*^{-/-}, and *Il10*^{-/-}*Il22*^{-/-} mice (10 male, 5 female per group, 12–16 weeks of age). Taxon-based analysis at **c** family level with **d** differentially expressed taxa by LEfSe analysis.

was associated with increased diversity compared to both WT ($p = 0.03$) and *Il10*^{-/-} mice ($p = 0.006$, Supplementary Table 4a). Similar results were obtained using the Shannon index, which measures richness and evenness of phylotypes (Supplementary Table 4b). These data support the histologic evidence that IL-22 deficiency appears to compensate for IL-10 deficiency in protecting *Il10*^{-/-}*Il22*^{-/-} mice against chronic colitis.

Principal component analysis of beta diversity using unweighted, UniFrac analysis, showed distinct clusters indicating distinct microbial community structures for each strain of mice (Fig. 7b). Analysis using permutational multivariate analysis of variance (PERMANOVA) demonstrated a significant effect on beta diversity by strain ($p = 0.001$), and pairwise adonis comparisons revealed significant differences between every combination ($p = 0.006$) with the exception of WT vs. *Il10*^{-/-} mice ($p = 0.078$). This suggests that together, IL-10 and IL-22 play an important role in regulating microbial diversity in the gut.

Taxon-based analysis revealed that the microbiome of each group comprised mainly of *Bacteroidetes*, *Firmicutes*, and *Proteobacteria* (Fig. 7c). At the family level, *Il22*^{-/-} and *Il10*^{-/-}*Il22*^{-/-} mice had fewer *Lactobacillaceae* and *Bacteroidaceae* compared to *Il10*^{-/-} mice. Figure 7d and Supplementary Table 5 lists significant differences between the four strains of mice from the phylum down through genus level, when detectable. The pathogenic potential of most of these organisms is not clearly understood, but some detected differences may be relevant to the *Il10*^{-/-} colitis model. Consistent with previous reports⁸ and similarly to IBD in humans,⁴⁸ species diversity was markedly reduced in the fecal microbiota of colitic *Il10*^{-/-} mice compared to WT. Of note *Il10*^{-/-} mice had increased abundance of the genus *Sutterella* which has been suspected to play a role in IBD pathogenesis.⁵³ In addition, an unknown genus within the family *Bacteroidaceae*, was more

common in *Il10*^{-/-} mice than WT, *Il22*^{-/-}, and *Il10*^{-/-}*Il22*^{-/-} mice which is consistent with reports where select members of *Bacteroidaceae* have been associated with colitis in humans and mouse models.⁵⁴ Interestingly, the genus *Bacteroides* was highest in the *Il10*^{-/-}*Il22*^{-/-} mice but was not associated with increased disease. Significantly, the *Helicobacter* genus was detected at the highest level in WT mice that did not develop colitis, as expected, and was detected at the lowest level in the feces of *Il10*^{-/-} mice with severe colitis (Fig. 7c) which is consistent with previous reports.⁵⁵

Taken together, these data suggest that without IL-10-mediated inhibition, IL-22 overexpression triggers excessive innate antimicrobial and tissue healing responses in the gut resulting in microbial dysbiosis, protracted tissue repair activity, and a state of chronic inflammation (Fig. 8). Importantly, these findings may also help to explain the surprising and disappointing failure of IL-17A-blocking drugs in clinical trials^{20,21,56} and shed new light on existing models of chronic intestinal inflammation.

DISCUSSION

To maintain intestinal health, the immune system must balance between tolerance to commensal microorganisms and defense against invading pathogens, and IL-17 and IL-22 play key roles in regulating host-protective responses at barrier surfaces. IL-22 facilitates the repair of damaged tissues by inducing regeneration of the intestinal epithelium,^{57,58} while IL-22 and IL-17A regulate innate antimicrobial responses to defend against enteric pathogens.⁵⁹ IL-10 acts in opposition by restricting host defense responses to prevent chronic inflammation and restore intestinal homeostasis.³ IL-10's anti-inflammatory role in the gut is well-established,^{4,8,11,60} however, it has been difficult to identify the

Fig. 8 Proposed role of the IL-10/IL-22 axis in intestinal homeostasis and chronic inflammation. **a** Under steady-state conditions in WT mice, Th17-axis cytokines (IL-23, IL-17A, IL-22) play a central role in regulating symbiosis between host and the intestinal microbiota by regulating the antimicrobial and tissue repair activities of IECs to control the growth of enteric bacteria, to maintain intestinal barrier integrity. Although the mechanism(s) are incompletely understood, IL-10 counterbalances these responses by restricting the expression of Th17-axis cytokines (including IL-22) to restore immune homeostasis. *Helicobacter* spp. are considered commensals and colonization does not trigger excessive inflammation or disease. **b** In *Il10*^{-/-} mice, *Helicobacter* spp. triggers the development of spontaneous colitis within 2–3 months of birth. Dysregulation of IL-17A/Th17 cells have been strongly implicated in disease pathogenesis but IL-22 is also aberrantly expressed. Many of the pathological features of colitis in IL-10-deficient mice, such as epithelial hyperplasia, overexpression of pro-inflammatory and antimicrobial genes, and dysbiosis of the intestinal microbiota, are consistent with unrestrained IL-22 production and sustained activation of IL-22-dependent tissue repair and antimicrobial pathways in the gut. **c** In *Il10*^{-/-}*Il22*^{-/-} double-deficient mice, animals are disease-free despite retaining high levels of Th17 cells and remaining colonized with *Helicobacter* spp. Expression of antimicrobial IL-22-target genes are normalized, excessive proliferation of the colonic epithelium is reversed and microbial diversity is reestablished (albeit with an altered composition compared to WT mice).

immune effector mechanism(s) that mediate intestinal pathology in IL-10-deficient models. A landmark study by Yen et al. in 2006 suggested that the IL-17/IL-23 (Th17) axis, not the previously implicated IL-12/IFN- γ (Th1) pathway, was responsible for intestinal disease.¹³ These data provided a compelling basis for the prevailing theory that pathogenic Th17 cells drive disease pathogenesis in IL-10-dependent models of intestinal inflammation. However, a growing number of conflicting studies report that intestinal inflammation is worsened by IL-17 depletion or occurs independently of IL-17.^{15,17–19} Taken together with the surprising failure of IL-17A or IL-17RA blocking antibodies to treat IBD in clinical trials,^{20,21} these findings suggest that unlike IL-17's pathogenic role in psoriasis,^{61,62} its contributions to intestinal pathology may be less clear.⁶³

Here, we provide evidence that IL-22 overexpression accounts for much of the immunopathology associated with spontaneous colitis in *Il10*^{-/-} mice and despite retaining high levels of Th17 cells in colonic tissues, *Il10*^{-/-}*Il22*^{-/-} double-deficient mice remained disease-free. Interestingly, while some groups have noted that IL-22, like IL-17, was markedly upregulated in IL-10/IL-10R-deficient mouse models of intestinal inflammation ironically, IL-22's role in disease pathogenesis was not addressed and disease activity was correlated with IL-17 upregulation.^{64,65} IL-10 receptor signaling was shown to play a role in controlling IL-22-dependent intestinal pathology in a T cell transfer model of colitis⁶⁶ and IL-10 has been shown to inhibit both IL-17 and IL-22 expression in vitro.⁶⁷ However, to our knowledge, it has not been

reported if IL-10/IL-17A-double-deficient mice develop colitis, which adds to the uncertainty of IL-17A's role in gut pathology. Importantly, Morrison and colleagues used *H. hepaticus*-infected anti-IL-10 receptor-treated mice to compare the contributions of IL-17A and IL-22 to acute colonic and cecal inflammation.⁶⁸ The authors found that IL-17A neutralization had no effect on colonic inflammation, but pathology in the cecum was exacerbated, while neutralization of IL-22 prevented inflammation in the colon, but not in the cecum. This study hinted at a pathogenic role for IL-22, and not IL-17, in IL-10-dependent acute colitis. Our data are in agreement with these findings and support a central role for an IL-10/IL-22-dependent axis of intestinal homeostasis.

Studies in *Il22*^{-/-} mice suggest that IL-22's role is largely protective in the gut⁶⁹ especially in the context of acute intestinal damage, such as during *Citrobacter rodentium* infection³¹ or in the dextran sulfate sodium (DSS)-induced colitis model.³³ Though ILC3s are an important early source of protective IL-22,²⁶ growing evidence in humans and mice suggests that chronic dysregulation of IL-22 and ILC3 responses in particular, results in intestinal pathology^{14,30,70–75} and even tumorigenesis.^{76,77} Accumulating data suggests that the distribution patterns of ILC3s within different intestinal tissues can dramatically impact host defense and tissue homeostasis.^{34,71,72} In the anti-CD40 model of acute colitis, the rapid redistribution of ILC3s from intestinal lymphoid structures precedes the development of inflammatory foci elsewhere in gut tissues⁷¹ that is dependent on IL-22-, but not IL-17A-expressing ILC3s.^{72,78} In addition, a recent report found that IL-22-

producing ILC3s accumulated in the small intestines of immunocompromised mice resulting in impaired host lipid metabolism.⁷⁹ In our study, while the levels of IL-22⁺ Th17 cells were slightly elevated in colonic tissues, we observed a sizeable accumulation of IL-22⁺IL-17A⁻ ILC3s selectively in the small bowel of *Il10*^{-/-} compared to WT mice. Although it is tempting to speculate, it is important to note that our data do not indicate how, or if the expansion of IL-22-producing ILC3s in the small intestine relates to the development of chronic colitis in *Il10*^{-/-} mice. Additional studies, will be required to parse out the potential role that IL-22⁺ILC3s, residing in the SI may play in chronic intestinal inflammation.

Indeed, the mechanisms by which ILC3s and IL-22 shape mucosal responses both locally and in distant tissues are poorly understood, but, direct and indirect mechanisms have been described.^{34,79,80} For instance, ILC3s communicate bi-directionally with innate cells, such as IECs, macrophages, and dendritic cells (DCs) via cytokines (such as IL-23, IL-22, GM-CSF) to quickly shape innate responses in response to changes in the tissue microenvironment.^{71,81,82} In addition, MHCII⁺ ILC3s have been shown to present antigens and directly regulate antimicrobial CD4⁺ T cell activity and T cell-dependent antibody production.^{83,84} Thus, despite being greatly outnumbered, ILC3s can employ various means to shape protective antimicrobial/tissue repair responses in the mucosa but more studies are needed to fully understand the underlying mechanism(s).

An important caveat, which has likely contributed to some confusion in the literature, is the inconsistent reporting of *Helicobacter* status in mouse colonies using IL-10-dependent models of colitis.⁸⁵ Neither germfree nor conventionally housed *Il10*^{-/-} mice develop spontaneous colitis,^{8,10} but rather, the development of intestinal disease is dependent on co-colonization with "pathobionts" such as *Helicobacter* spp.^{9,55} *Helicobacter*-colonized *Il10*^{-/-} mice are easily identified clinically by the appearance of rectal prolapse,⁸⁶ but in most other mouse strains infection is non-pathogenic or subclinical^{8,10,37} and frequently, *Helicobacter* status is unknown.⁸⁷ Pups acquire their intestinal microbiota through fecal-oral contact⁷ and depending on the breeding strategy and status of the parental strains, the *Helicobacter* status of pups needs to be tested to confirm transmission, otherwise, the results may be confounded.³⁷ Notably, Yen's study did not report *Helicobacter* status of their mouse colonies, thus it is not clear if the resolution of colitis in *Il10*^{-/-}*p19*^{-/-} mice is due to the lack of IL-23 or *Helicobacters*.¹³ Similarly, *Il10*^{-/-}*Il17a*^{-/-} mice were previously generated but neither the *Helicobacter* status nor the incidence of intestinal disease was reported although these studies were focused on IL-17A's role in lung pathology.^{88,89} Here, we confirmed that *Il10*^{-/-}*Il22*^{-/-} mice remained colonized with *Helicobacter* spp. (Fig. 7) yet were disease free which strengthens our assertion that IL-22 is a critical effector cytokine driving the development of colitis in *Il10*^{-/-} mice.

In both humans^{90,91} and IL-10-dependent models of colitis,^{8,50} IBD is associated with reduced diversity of the intestinal microbiome, yet it remains unclear if microbial dysbiosis is a cause or result of intestinal inflammation.⁹² IL-22 has a vital role in shaping the commensal microbiota and protecting against enteric pathogens.^{80,93,94} In line with this, we observed that microbial diversity was restored in our *Il10*^{-/-}*Il22*^{-/-} mice suggesting that dysregulation of the ILC3/IL-22 axis drives microbial dysbiosis in *Il10*^{-/-} mice. As mentioned previously, IL-22-producing ILC3s were found to gather in the small intestines of WT and *Rag1*^{-/-} weanlings as they become colonized with commensals. In WT pups, the ILC3s were soon displaced by adaptive immune cell populations, but in *Rag1*^{-/-} mice the levels of activated ILC3s remained elevated in resulting in altered homeostasis in gut tissues.⁷⁹ The *Helicobacter* status of the mice in this study was not reported, but interestingly, work from others demonstrated that, like in *Il10*^{-/-} mice, colonization of *Rag*-deficient mice with *Helicobacter* spp. results in spontaneous colitis.^{95,96} Importantly,

the development of colitis in *Helicobacter*-infected *Rag*^{-/-} mice was shown to be dependent on IL-22.⁹⁷ It is important to note that our data do not indicate if the microbiota itself is sufficient to induce or protect against the development of spontaneous colitis. Additional studies will be needed to determine this. Together, these converging data along with our findings that microbial diversity is restored in *Il10*^{-/-}*Il22*^{-/-} mice, suggest that IL-10 plays an underappreciated role in establishing mutualism by regulating innate IL-22 responses to commensal bacteria and promoting the development of tolerogenic adaptive immune subsets.⁸⁰

This study highlights the mechanistic connection between IL-10 and IL-22 and offers important insights into the pathogenesis of chronic colitis in *Il10*^{-/-} mice. Our data suggest a model in which IL-10 and IL-22 form a regulatory axis within the gut mucosa to maintain intestinal health. Thus, in the context of IL-10-deficiency, IL-22 is necessary while IL-17 is not sufficient to drive immune-mediated intestinal pathology. Importantly, the IL-10/IL-22 axis also provides a conceptual framework to link the development and resolution of intestinal inflammation with the mechanisms underlying epithelial repair. These findings may help to reconcile conflicting reports regarding IL-17's role in intestinal disease and will be informative when considering new therapeutic approaches in IBD and other inflammatory disorders.

MATERIALS AND METHODS

Mice

B6.129P2-*Il10*^{tm1Cgn} (*Il10*^{-/-}) as well as WT mice were originally obtained from Jackson Laboratories (Bar Harbor, ME) and have been maintained in separate breeding colonies within our animal facility for over 14 years. *Il22*^{-/-} mice were obtained through an agreement with Genentech and have been maintained in separate breeding colonies within the same facility for over 7 years. The *Il10*^{-/-}*Il22*^{-/-} mice were generated in our facility through inter-crossing *Il10*^{-/-} and *Il22*^{-/-} mice. To examine IL-22's role in regulating disease pathology and microbial diversity in *Il10*^{-/-} mice, it was important to control for potential founder effects by generating mice genetically deficient in *Il10* and *Il22* while maintaining the microbiota from *Il10*^{-/-} mice. To do so, we used a breeding strategy which minimizes microbial cross-contamination.⁹⁸ Briefly, we set up clean breeding cages with one female *Il10*^{-/-} mouse in estrus and one male *Il22*^{-/-} breeder and once impregnated, the female *Il10*^{-/-} mouse was separated from the male and placed into a clean cage. For the F2 generation, a female *Il10*^{-/-} mouse and a F1 male *Il10*^{+/+}*Il22*^{+/-} breeder were placed in a clean cage, and the impregnated female was separated from the male and placed into a clean cage. *Il10*^{-/-}*Il22*^{-/-} F2 mice were maintained then by interbreeding.

For experimental procedures male animals between 16 and 20 weeks of age were used unless stated otherwise. Mice on study were housed in individually ventilated cages (Allentown Caging Equipment, Allentown, PA), containing autoclaved corncob bedding (Harlan Teklad, Indianapolis, IN) with a cotton-enrichment square. Mice were provided autoclaved rodent chow ad libitum (Harlan Teklad, Indianapolis, IN) and received reverse-osmosis-treated, hyperchlorinated water via automated in-cage watering system (Edstrom Industries, LLC, Waterford, WI). The room was maintained on a 14:10 h light:dark cycle at 22.8 ± 2 °C, with relative humidity between 30% and 50%. All experimental procedures were approved by the Johns Hopkins University Animal Care and Use Committee, the program is accredited by AAALAC, International and procedures were consistent with the *Guide for the Care and Use of Laboratory Animals*.

mRNA isolation and quantitative RT-PCR analyses

Total RNA was isolated from spleen, mesenteric lymph node (MLN), terminal ileum and proximal and distal colon using TRIzol (Invitrogen, Carlsbad, CA) according to the manufacturer's

protocol. Reverse transcription was performed using a first strand cDNA synthesis kit (Roche, Indianapolis, IN). Quantitative PCR was performed using SYBR Green gene-specific primers on an ABI 7300 Real-time PCR System. Results were normalized to *Gapdh* levels. For relative comparisons, samples were compared to the corresponding WT tissue that was assigned an arbitrary value of 1.

Isolation of intraepithelial lymphocytes (IELs) and lamina propria lymphocytes (LPLs)

IELs and LPLs were isolated as described previously.¹ Briefly, colons and small intestines were harvested, cut open longitudinally and washed in cold 1xPBS to remove feces. Either two small intestines or three colons were cut into 1 cm segments and incubated for 25 min at 37 °C in RPMI containing 3% FBS, EDTA, DTT, and Hepes, with shaking. Suspensions were strained and IELs were purified from the flow through using a percoll gradient. The remaining segments of small intestine and colon were further digested in RPMI containing DNaseI, Liberase TL, and Hepes for 50 min at 37 °C. The digested tissues were passed through a 70 µm and a 40 µm strainer, respectively, to obtain single cell suspensions of small intestinal and colonic LPLs. All procedures were carried out on ice.

Cell staining, antibodies, and flow cytometry

For cellular phenotyping, cells were washed, incubated with anti-CD16 to block Fc receptors and stained with VIVID (Invitrogen, Carlsbad, CA) to exclude dead cells. Cells were surface stained in cocktails with different combinations of fluorescent dye-conjugated monoclonal antibodies (mAbs) depending on the panel that included antibodies raised against CD3ε, CD4, CD8, CD19, CD11b, Ly6C, Ly6G, F4/80, NKp46, CD127 (IL-7Rα), CCR6 and γδTCR (BD Biosciences, San Jose, CA). For intracellular cytokine staining (ICS) experiments, single cell suspensions of spleen, MLN, small intestinal IELs (sIEL) and sLPLs, colonic IELs (cIEL) and cLPLs were re-stimulated for 4 h with 40 ng/mL phorbol-12-myristate-13-acetate (PMA) and 2 µg/mL ionomycin (Millipore, Billerica, MA, USA) in the presence of brefeldin A (BD Biosciences, San Jose, CA). Cells were surface stained as above then were fixed and permeabilized using the eBioscience Foxp3 buffer system and stained with antibodies against mouse IL-10, IFN-γ, IL-17, IL-22, RORγt, and/or Foxp3 (BD Biosciences, San Jose, CA). Cells were acquired on a BD LSRII. Data were analyzed with FlowJo software (Tree Star, Ashland, OR).

Tissue explants

Colons and small intestines were harvested, cut open longitudinally and washed in cold 1xPBS to remove gut contents. For the colon, two 1 cm segments from the distal, mid, and proximal regions as well as the cecum were cut, weighed, and washed three additional times in sterile cold PBS. For the small intestine, two 1 cm segments from the midpoint were used. After washing, explants were cultured in a 24-well plate for 24 h in 500 µL of complete IMDM media supplemented with 10% fetal bovine serum (FBS, Atlanta Biologicals, Inc. Flowery Branch, GA), 2 mM of L-glutamine (Cellgro®, Mediatech, Inc., Manassas, VA), 1X of non-essential amino acids (Gibco®, Life Technologies, Grand Island, NY), 1 mM of sodium pyruvate (Gibco®, Life Technologies, Grand Island, NY), 10 mM of 2-mercaptoethanol (Gibco®, Life Technologies, Grand Island, NY), 100 U/mL of penicillin (Cellgro®, Mediatech, Inc., Manassas, VA), and 100 mg/mL of streptomycin (Cellgro®, Mediatech, Inc., Manassas, VA). Supernatants were collected, centrifuged to eliminate debris and stored at -80 °C until analysis.

IL-22 ELISA

IL-22 in serum and colon explant supernatants was measured using the Mouse IL-22 ELISA MAX™ Deluxe (Biolegend, San Diego, CA) according to the manufacturer's protocol.

Ig ELISA

Freshly collected or frozen fecal samples were suspended at a 100 mg/mL in PBS containing 0.1% Tween 20 and Complete Mini (one tablet per 10 mL, Roche, Mannheim, Germany). Samples were vortexed until a homogenous suspension was obtained and allowed to sit at room temperature for 20 min. Samples were centrifuged for 10 min at 12,000 rpm at 4 °C. The clear supernatant was collected and stored at -20 °C until analysis. Fecal IgA and IgG were measured by ELISA as described previously.⁹⁹ ELISA plates were coated overnight at 4 °C with goat anti-mouse Ig (Southern Biotech, Birmingham, AL), then washed and blocked with 1% BSA-PBS (30 min at room temperature). Serial dilutions of fecal supernatants were added to the 96-well plates, followed by HRP-conjugated, isotype-specific, secondary antibodies (1:1000 dilution in PBS-BSA; Southern Biotech, Birmingham, AL).

Pathology

Mice were monitored weekly for rectal prolapse. For histopathology, euthanasia was performed by CO₂ inhalation, then exsanguination and blood collection by cardiocentesis. Mice were perfused with heparinized saline, followed by 10% neutral buffered formalin, via the left ventricle of the heart. Colons were collected, and either cut open longitudinally and prepared as a "Swiss roll", or as cross sections. Fixed tissues were processed routinely to paraffin in graded alcohols, sectioned at 5 µm, and stained with hematoxylin and eosin (H&E). Inflammation was scored in a blinded manner according to The Jackson Laboratory (TJL) scoring system as described previously.¹⁰⁰

PCR array

Total RNA was isolated from the distal colons of WT, *Il10*^{-/-}, *Il22*^{-/-}, and *Il10*^{-/-}*Il22*^{-/-} mice (*n* = 4) using TRIzol (Invitrogen), according to the manufacturer's protocol. RNA was reverse-transcribed using the High Capacity cDNA Reverse Transcription Kit (Applied Biosystems). cDNA samples were then loaded onto the TaqMan™ OpenArray™ Mouse Inflammation Panel (Applied Biosystems) using the QuantStudio 12K Flex OpenArray AccuFill System (LTI). OpenArray Real-Time PCR results were analyzed using Partek genomic software. Gene expression was calculated using the comparative Cq method as fold change relative to WT using the reference gene *Hprt1*. Significantly different genes were calculated using ANOVA with cutoff at FDR < 0.05 and fold change of 2. Data were visualized as heatmaps composed of Z-scores from standardized Cq values for each independent sample.

Bacterial 16s rRNA sequencing and qPCR

The fecal microbiome was analyzed using feces from 10 male and 5 female mice of each genotype obtained between 12 and 16 weeks. DNA was extracted from fecal pellets using the PowerSoil DNA Kit (MO BIO Laboratories, Carlsbad, CA). Amplicons were generated using oligonucleotide primers that target ~300 bp of the V4 variable region of the 16s rRNA gene (primers 515F and 806R)¹⁰¹ and also were barcoded and pooled to construct the sequencing library, followed by sequencing with an Illumina MiSeq instrument to generate paired-end 150 × 150 reads. The software package QIIME 1.7.0 was used to analyze, display, and generate figures of microbiome data using a previously defined method.¹⁰²

Overlapping pair-end reads were aligned using SHE-RAX¹⁰³ with subsequent analysis and normalization performed using QIIME 1.7.0.¹⁰⁴ Fecal communities were compared by using UniFrac, a phylogeny-based distance metric that measures the degree to which any two microbiota share branch length on a bacterial tree of life. As a first step, sequence data and metadata were combined to de-multiplex the barcoded reads followed by quality filtering using the default parameters in QIIME. Sequences were grouped into operational taxonomic units (OTUs) at 97% sequence similarity using the UCLUST algorithm. Taxonomy was assigned

using Ribosomal Database Project (RDP) classifier against the GreenGenes database, and sequences were aligned and a phylogenetic tree was built from reference sequences using FastTree. An OTU table showing counts of each OTU in each sample was produced. To control for differences in sequencing depth, OTU tables were rarified at a single sequencing depth.^{105,106} Alpha diversity was determined using the Shannon and Chao1 indices, and statistical analysis was performed at a sampling depth of 30,450 sequences. Beta diversity was determined using unweighted and weighted UniFrac distance matrices¹⁰⁷ and the results presented as principal coordinate axis (PCoA) plots. Significant differences in the relative abundance of bacteria at different taxonomic levels were computed using Linear Discriminant Analysis Effect Size (LEfSe) comparing each mouse strain against the remaining samples with LDA scores > 2.0 and *p*-values < 0.05 considered significant.¹⁰⁸ Pairwise adonis comparisons were carried out using RStudio (version 3.4.3) with the pairwiseAdonis package.¹⁰⁹

Statistical measures of microbiota diversity

Data were analyzed at the highest sampling depth (30,450 reads) that was shared by all four genotypes of mice. All statistical analyses ($\alpha = 0.05$) were performed using GraphPad Prism 5 (GraphPad Software, La Jolla, CA). If data were normally distributed based on the Kolmogorov-Smirnov test, groups were compared using one-way ANOVA and *p*-values generated using the Student-Neuman-Keuls multiple comparison procedure. If data sets were not normally distributed, due to either skew or non-continuous nature (histopathology metrics), the Mann-Whitney *U* test, Kruskal-Wallis test or Dunn's multiple comparison procedure were used. Array findings were reported when the *p* value and the FDR were both < 0.05.

ACKNOWLEDGEMENTS

We thank Tricia Nilles and the Becton Dickinson Immune Function Lab in the Johns Hopkins School of Public Health (JHSPH) for assistance with flow cytometry, the Johns Hopkins Phenotyping Core and Nadine Forbes-McBean for assistance with pathology, and the Johns Hopkins Oncology Tissue Services (OTS) for histology processing. We thank Roxann Ashworth of the JHU Genetic Research Core facility for running the OpenArrays and Anne E. Jedlicka and Amanda Dziedzic of the JHSPH Genomic Analysis and Sequencing Core Facility for assistance with OpenArray data analysis. We thank Drs. Alan Scott, Fengyi Wan, and Bruce Horwitz for careful review of this manuscript. This work was supported in part by grants to J.H.B. from the National Institutes of Health (NIH) (R01AI070594 and R01AI113910) and to J.G.F. (T32OD 010978-28, R01OD011141, and P30ES002109). D.C.G. was supported in part by the Molecular and Cellular Basis of Infectious Diseases (MCBID) training grant from the NIH (T32AI007417-23). V.V. is supported by a scholarship from H.R.H. Maha Chakri Sirindhorn (Thailand).

AUTHOR CONTRIBUTIONS

D.C.G., A.R., and J.H.B. conceived the study, designed experiments. D.C.G. and J.H.B. wrote the manuscript. A.R., P.U., J.M., P.S., V.V., Z.S. and A.S. performed experiments. D.C.G., M.T.W., C.F.B., J.G.F., V.V., A.S. and J.H.B. interpreted results and/or generated figures. C.F.B., M.T.W. and J.G.F. provided feedback and supervised certain aspects of the study.
