Neurological side effects arising from chemotherapy, such as severe pain and cognitive impairment, are a major concern for cancer patients. These major side effects can lead to reduction or termination of chemotherapy medication in patients, negatively impacting their prognoses. With cancer survival rates improving dramatically, addressing side effects of cancer treatment has become pressing. Here, we use iPSC-derived human neurons to investigate the molecular mechanisms that lead to neurotoxicity induced by vincristine, a common chemotherapeutic used to treat solid tumors. Our results uncover a novel mechanism by which vincristine causes a local increase in mitochondrial proteins that produce reactive oxygen species (ROS) in the axon. Vincristine triggers a cascade of axon pathology, causing mitochondrial dysfunction that leads to elevated axonal ROS levels and SARM1-dependent axon degeneration. Importantly, we show that the neurotoxic effect of increased axonal ROS can be mitigated by the small molecule mitochondrial division inhibitor 1 (mdivi-1) and antioxidants glutathione and mitoquinone, identifying a novel therapeutic avenue to treat the neurological effects of chemotherapy.

## INTRODUCTION

Vincristine is a widely used chemotherapeutic agent for treating solid tumors in children and adults [1]. However, its use at high doses in patients is restricted by its potential to cause chemotherapy-induced peripheral neuropathy (CIPN) [2]. CIPN is a debilitating and sometimes irreversible condition with symptoms including chronic neuropathic pain, muscle weakness, and sensory loss [1]. The emergence of CIPN symptoms often leads to a reduction or premature discontinuation of cancer treatment. To date, there is no reliable way to predict which patients may develop CIPN. Often, CIPN symptoms worsen once treatment is completed, leaving little opportunity to adjust chemotherapy frequency or dose level [3]. Currently, there are limited palliative treatment options and no cure for CIPN.

Another type of neurological side effect of chemotherapeutics such as vincristine involves cognitive and memory deficits commonly referred to as chemo brain [4–6]. This suggests that central as well as peripheral neurons can be negatively affected by chemotherapy. With cancer survival rates improving significantly over the last decades, an unintended consequence is more people living with chronic pain. Thus, there is a pressing need to find effective interventions to manage vincristine-induced neurological symptoms in the growing number of affected patients [7].

Vincristine is an anti-mitotic agent that binds with high affinity to the tubulin in microtubules of the mitotic spindle and impedes cancer cell division [8]. However, vincristine also binds to microtubules of the axonal cytoskeleton, disrupting axonal transport and inducing axon degeneration by blocking microtubule polymerization [9]. In mice, vincristine treatment has been

shown to cause mitochondrial transport dysfunction [10] and swelling [11], leading to increased levels of reactive oxygen species (ROS) in the soma [12]. These downstream consequences of axonal damage are potential contributors to the high incidences of neurological side effects in patients who receive treatment with vincristine.

Numerous studies have modeled vincristine-induced axon degeneration with in vitro assays in mouse dorsal root ganglia cultures [1, 10, 13, 14]; however, these are limited by scalability and possibly also by translational relevance to human patients. Using human neurons to find potential therapeutic interventions for neurological side effects of chemotherapy is therefore highly desirable. Inducible pluripotent stem cell-derived neuron (iPSN) technology, in addition to being human in origin, affords the production of sufficient quantities of neurons to perform large-scale analyses. Importantly, iPSNs have been used to model vincristine-induced neurotoxicity and to screen for potential therapeutic candidates [15, 16], paving the way for mechanistic studies.

In this study, we investigate the effects of vincristine on axonal health using a validated transcription factor-mediated platform to generate human neurons from iPSCs (inducible, isogenic, and integrated i<sup>3</sup>Neurons [17]). To identify the molecular changes that occur in human axons directly after localized exposure to vincristine, we perform mass spectrometry of i<sup>3</sup>Neuron axons and detect an early increase in mitochondrial and electron transport chain-related proteins. We determine that even low doses of vincristine cause mitochondrial dysfunction, increases in ROS, and mild axon degeneration. This degeneration depends on

SARM1, a key executioner protein of axon degeneration [18, 19]. We find that the toxic effects of vincristine can be ameliorated by mitochondrial division inhibitor 1 (mdivi-1), a small molecule reported to inhibit dynamin-related protein 1 (DRP1) and potentially interfere with mitochondrial respiratory complex I. We demonstrate that treatment of neurons with mdivi-1 or antioxidants such as glutathione and the mitochondrial-targeted ubiquinone derivative (mitoquinone or MitoQ) reduces ROS and confers neuroprotection in the axons of human iPSC-derived neurons after vincristine treatment. We unexpectedly find that mdivi-1 mitigates vincristine-induced axon degeneration independently of DRP1, implicating the reduction of ROS as a key target for the treatment of vincristine-induced neurotoxicity.

## RESULTS

### Low doses of vincristine induce axon degeneration in human neurons

To investigate the effects of vincristine on human neurons, we used a transcription factor-mediated platform to generate human  $i^3$ Neurons.  $i^3$  iPSCs are engineered with a doxycycline-inducible promoter to direct expression of the transcription factor NGN2 (neurogenin-2) which drives their differentiation into glutamatergic cortical-like neurons. Addition of doxycycline to the cell culture media causes iPSC differentiation into human  $i^3$ Neurons in an efficient, scalable, and reproducible manner in 10 days [17] (Fig. 1A). Vincristine is known to cause axon degeneration *in vitro* and *in vivo* in mice [20]. To measure the effect of vincristine on human axon health, iPSCs were plated in the center of a well such that axons grew outwards, enabling the formation of a distinct axon-enriched region (Fig. 1B). Neurons were grown for 10–14 days before treatment with 5 nM vincristine, a physiologically relevant dose [21]. Axonal integrity was assessed by adapting a published method to quantify axon degeneration (Supplementary Fig. 1) [22]. Significant axon degeneration was observed 8 and 24 h after vincristine treatment (Fig. 1C, D), consistent with previous results obtained in primary neurons from mouse. Thus,  $i^3$ Neurons are a robust and scalable system to investigate the toxicity of vincristine in human neurons.

### Mass spectrometry of $i^3$ Neuron axons reveals vincristine-induced mitochondrial deficits

We predicted that vincristine application would cause acute protein changes in axons. Therefore, we locally applied vincristine just to the axons and selectively purified this cellular compartment for unbiased mass spectrometry analyses. Neurons were plated in Boyden chambers (Fig. 1E) which allow axons to grow through a porous membrane and be cleanly isolated from somas, as assessed by the absence of the nuclear protein Lamin A in the axonal fraction (Fig. 1F). Using this platform, we compared control axons treated with DMSO with those selectively treated with 5 nM vincristine. After 4 h, the axonal and cell body compartments were harvested and subjected to label-free mass spectrometry. In total, 3441 proteins were identified, with 766 enriched in soma and 224 in axons (Supplementary Fig. 2A, Supplementary File 1). Gene ontology analysis of proteins significantly enriched in the cell body highlighted proteins involved in RNA catabolic process, translation initiation, and RNA splicing (Supplementary Fig. 2B). Conversely, proteins involved in axonogenesis, synapse organization, and axon guidance were enriched in the axonal fraction (Supplementary Fig. 2C). These results validated our approach to efficiently isolate axons from the cell bodies and provide a rich dataset to investigate protein level changes during CIPN.

When comparing vincristine- to DMSO-treated axons, 63 enriched and 12 depleted proteins were identified (>2 unique peptides detected, fold change >1.5, adjusted *P*-value < 0.05, Fig. 1G, Supplementary File 1). We validated the increase of three of these proteins: cytochrome C, NDUFB9 and NDUFA12, by Western

blot from axonal lysates after vincristine treatment (Supplementary Fig. 2D–I). Notably, gene ontology analysis revealed that a significant fraction of the upregulated proteins was mitochondrial (23/63; 36%) (Fig. 1H) and involved in ATP synthesis or oxidative phosphorylation (Fig. 1I). String analysis was performed to create a protein–protein interaction network of vincristine-induced upregulated proteins. This analysis showed that many of the enriched mitochondrial proteins are known to interact (Fig. 1J, red). Interestingly, we observed a largely connected cluster that is associated with the electron transport chain, an intensive site of ROS production [23] (Fig. 1J, blue). This led us to hypothesize that vincristine causes axon degeneration by impairing axonal mitochondrial function and inducing oxidative stress through the overproduction of ROS [23].

### Vincristine causes mitochondrial dysfunction and increased ROS in $i^3$ Neuron axons

We next addressed the effect of vincristine on mitochondrial function. Mitochondrial health can be evaluated by measuring cellular oxygen consumption rates using a Seahorse metabolic flux assay. Exposing neurons for 4, 8, and 24 h to 5 nM vincristine caused basal respiration levels to drop significantly for the next 24 h (Fig. 2A, B). These data demonstrate that a major effect of vincristine is impairment of normal mitochondrial function in neurons.

Mitochondrial dysfunction is known to result in an increase in ROS [23]. Additionally, our mass spectrometry results showed that proteins involved in oxidative phosphorylation as well as those involved in the catalysis of ROS (SOD2, PRDX3, GLRX and TXNDC17) were increased after axonal exposure to vincristine. We hypothesized that vincristine causes a local increase in the levels of ROS in human axons leading to axon degeneration. To measure the levels of ROS in axons, neurons were incubated with dihydroethidium (DHE), a cell-penetrable fluorescent indicator of ROS in the cytoplasm [24]. Treatment of  $i^3$ Neurons with vincristine resulted in a significant increase in axonal ROS levels at 4, 8, and 24 h after treatment (Fig. 2C, D).

Mitochondrial dysfunction and cellular stress can also lead to an increase in mitochondrial superoxide species. We hypothesized that a significant proportion of the observed increase in total axonal ROS levels would be accounted for by mitochondrial ROS. Mitochondrial ROS levels in the axon were indeed increased 4, 8, and 24 h after exposure to vincristine as measured by MitoSOX (Fig. 2E, F). Taken together, these results demonstrate that vincristine induces mitochondrial dysfunction and leads to an increase in total and mitochondrial ROS levels in axons.

### Mdivi-1 inhibits vincristine-induced axon degeneration

We hypothesized that inhibiting ROS generation may delay axon degeneration. To test this, vincristine-treated neurons were exposed to the small molecule mdivi-1. Mdivi-1 is often described as a DRP1 inhibitor and has been utilized in the context of neuronal injury to attenuate traumatic brain injury-induced cell death [25], protect against glutamate excitotoxicity and oxygen-glucose deprivation [26], and reduce cerebral damage caused by ischemia/reperfusion injury [27]. However, it has also been shown to reduce ROS production in neurons [28]. Through this mechanism, mdivi-1 has conferred neuroprotection by suppressing the mitochondrial apoptosis pathway and decreasing ER stress and ROS-mediated oxidative stress [29].

When we treated neurons with 50  $\mu$ M mdivi-1 in addition to 5 nM vincristine, axon degeneration was significantly reduced by two-fold after 24 h compared to neurons treated only with vincristine (Fig. 3A, B). We next asked whether mdivi-1 acts locally on the axon, or whether application to the whole cell is required for its protective effect. To test this, neurons were grown in microfluidic chambers to physically isolate axons from cell bodies (Fig. 3C). Vincristine, mdivi-1, or their combination was added to

membrane due to its high affinity for phosphatidylserine, which undergoes externalization during apoptosis [30, 31]. An increase in the levels of Annexin V fluorescence correlates with apoptotic cell death, or in this case, externalization of axonal membrane and axon degeneration. Center-plated neurons were treated with vincristine and mdivi-1 for 24 h and then stained with Annexin V. Neurons treated with vincristine had significantly greater levels of Annexin V staining than untreated neurons (Fig. 3F, G). Mdivi-1 significantly reduced Annexin V staining (Fig. 3F, G). These data demonstrate that axonal exposure to vincristine is sufficient to cause axon degeneration that can be mitigated by mdivi-1.

#### Preventing mitochondrial fission does not delay vincristine-induced axon degeneration

Because mdivi-1 has been used as an inhibitor of DRP1 and thus of mitochondrial fission [32], we asked whether inhibiting mitochondrial fission would reduce vincristine-induced axon degeneration. To knock down DRP1,  $i^3$  iPSCs containing dCas9 gene silencing machinery were transduced with gRNAs to DNMT1 (which encodes DRP1) or controls [33]. Using this approach, an 80 percent reduction in the DRP1 transcript levels was measured by qPCR (Fig. 4A). DRP1 knockdown was functionally confirmed in mature neurons by measuring the mitochondrial size in control and DRP1 knockdown (KD) neurons (Fig. 4B, C). As expected, DRP1 KD neurons had significantly larger mitochondria (~60% increase) (Fig. 4B, C), validating that the knockdown of DRP1 in  $i^3$ Neurons impairs mitochondrial fission.

We next treated control and DRP1 KD neurons with vincristine. Inhibiting mitochondrial fission via DRP1 knockdown failed to delay or reduce vincristine-induced axon degeneration (Fig. 4D, E). Moreover, DRP1 phosphorylation (p-S616), a marker of increased mitochondrial fission [34], was not increased after vincristine treatment (Supplementary Fig. 3A, B and Supplementary Fig. 5). Vincristine treatment caused axonal mitochondria to decrease in size 8 h after vincristine treatment (Supplementary Fig. 3E) but did not increase the number of axonal mitochondrial particles (Supplementary Fig. 3C, D) as would be expected if it induced mitochondrial fission. Finally, treatment of DRP1 KD neurons with mdivi-1 resulted in a significant reduction in vincristine-induced axon degeneration after 24 h (Fig. 4F, G). Together, our results demonstrate that vincristine does not induce mitochondrial fission in  $i^3$ Neurons and inhibiting mitochondrial fission does not delay vincristine-induced axonal degeneration. We therefore conclude that mdivi-1 delays axonal degeneration via a DRP1-independent mechanism.

#### Mdivi-1 reduces vincristine-induced axonal ROS levels

Mdivi-1 has recently been shown to act not by inhibiting DRP1, but instead by inhibiting ROS production in mitochondria [28, 35–37]. We therefore evaluated whether mdivi-1 treatment

would result in a decrease in axonal ROS levels.  $i^3$ Neurons were treated with vincristine alone or concurrently with mdivi-1 for 4, 8, and 24 h, and at each timepoint, concurrent treatment with vincristine and mdivi-1 resulted in a significant decrease in axonal ROS levels measured by DHE compared to treatment with vincristine alone (Fig. 5A, B). Additionally, mdivi-1 significantly reduced the levels of mitochondrial ROS 8 and 24 h after vincristine treatment (Fig. 5C, D). Here we demonstrate that mdivi-1 delays vincristine-induced axonal degeneration by reducing the levels of ROS and not by inhibiting mitochondrial fission.

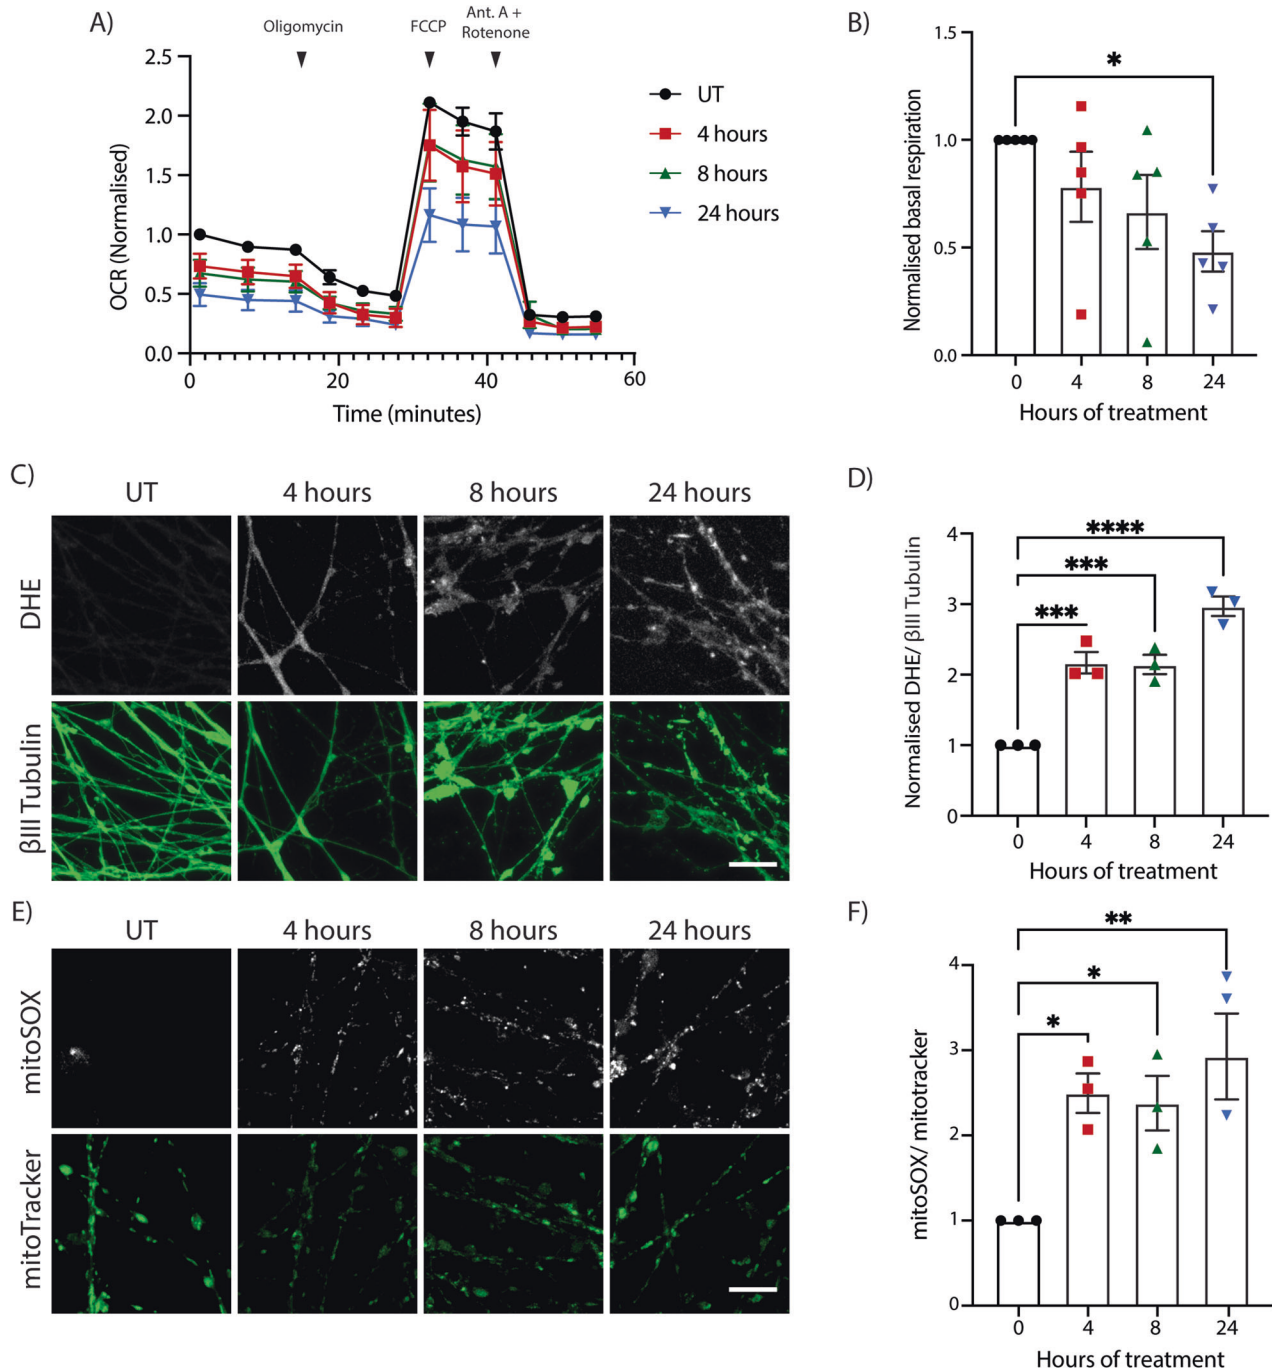

To further test whether reducing ROS prevented axon degeneration, neurons were treated with two potent antioxidant agents that have been shown to inhibit ROS after neuronal stress; glutathione (GSH) [38] and mitoquinone (MitoQ) [12, 39]. As expected, treatment with GSH or MitoQ almost completely abolished vincristine-induced ROS generation in the axons after 24 h (Fig. 5E, F). Furthermore, GSH and to a lesser extent MitoQ were able to delay vincristine-induced axon degeneration (Fig. 5G, H). These results demonstrate that inhibition of ROS in axons can reduce vincristine-induced axon degeneration.

#### Mitochondrial dysfunction and ROS production lies upstream of SARM1

Mitochondrial dysfunction and an increase in ROS levels have been shown to lie upstream of sterile  $\alpha$  and TIR motif containing 1 (SARM1) to cause axon degeneration in the cell bodies of mouse neurons in vitro [18]. To confirm this in human axons in response to vincristine, we generated SARM1 KO iPSCs using CRISPR/Cas9 gene editing (Supplementary Fig. 4). Wildtype and SARM1 KO neurons were treated with 5 nM vincristine for 4, 8, and 24 h. Deletion of SARM1 significantly reduced axon degeneration approximately two- and four-fold 8 and 24 h after vincristine treatment, respectively, compared to wildtype neurons (Fig. 6A, B). To confirm that SARM1 was acting downstream of the ROS increase caused by vincristine, we measured ROS levels in wildtype and SARM1 KO neurons. We found no significant difference in the levels of total axonal ROS (Fig. 6C, D) or mitochondrial ROS levels (Fig. 6E, F) between wildtype and SARM1 KO neurons in response to vincristine treatment. Taken together, our results show that mitochondrial dysfunction and an increase in ROS levels in the axon lie upstream of SARM1 activation and axon degeneration in human neurons.

#### DISCUSSION

In the present study, we validate  $i^3$ Neurons as a highly translatable model for studying vincristine-induced axon degeneration. We demonstrate that increases in mitochondrial proteins involved in oxidative phosphorylation and increase of ROS in the axon are

early molecular events in response to vincristine. We uncover a novel mechanism by which vincristine causes mild mitochondrial dysfunction, leading to increased levels of ROS in the axon and SARM1-dependent axon degeneration. Additionally, we show that

mdvi-1 and other antioxidants reduce vincristine-induced axon degeneration by decreasing levels of ROS in the axon (Fig. 7).

Previous studies have used iPSC-derived neurons to model the effect of vincristine on neuronal survival [15, 40–45]. However,

these studies typically used much higher doses of vincristine (50 nM–1  $\mu$ M) than levels that have been measured in cerebral spinal fluid of human patients after vincristine treatment (~0.1–2 nM) [21, 46]. This discrepancy of 25–500-fold in vincristine dose level calls into question the ability of previous studies to accurately model the effects of vincristine on neuronal health. In our study, we used 5 nM vincristine which is much closer to the actual levels measured in patients undergoing chemotherapy.

Vincristine is known to cause mitochondrial depolarization [47], but the mechanism by which this happens remains poorly understood. We found that vincristine acts locally to increase the levels of axonal mitochondrial proteins that constitute complex I of the electron transport chain involved in oxidative phosphorylation and catalysis of ROS. This correlates well with our observed increase in the levels of axonal ROS. However, the rates of oxidative phosphorylation were unchanged 4 h after vincristine treatment, as measured by the Seahorse assay. We hypothesize

that the enrichment in mitochondrial proteins may be an adaptive response to mitochondrial dysfunction caused by vincristine in the axon, since increased assembly of complex I would be predicted to result in a reduction of ROS [48]. Elevated ROS levels have been reported in the spinal cord of mice treated with vincristine [12]

and in the brains of patients that undergo chemotherapy [5]. We observed increased levels of total and mitochondrial ROS in the axon as early as 4 h after vincristine treatment, in agreement with these studies. Interestingly, since the changes in protein levels happened on the scale of just a few hours after the addition of

vincristine, it is possible that they arise from local regulation in the axon (such as protein stabilization or local translation). Vincristine's disruption of the microtubule cytoskeleton, which impairs retrograde axonal cargo transport [49, 50], might contribute to the increase in ROS observed. Damaged mitochondria may not be properly retrogradely transported to the soma for degradation and/or fusion with other healthy mitochondria, which can lead to their accumulation in axons and an increase in ROS levels. Since we have shown that reducing ROS levels reduces vincristine-induced axon degeneration, unraveling the mechanism by which ROS are increased in  $i^3$ Neurons merits future investigation.

Our observation that SARM1 knockout does not prevent accumulation of axonal and mitochondrial ROS is in line with previous studies placing ROS production and mitochondrial depolarization upstream of SARM1 activation (Fig. 6C–F). Mitochondrial ROS has been shown to mediate calcium influx into the cell after both sensory nerve axotomy and CCCP-induced SARM1-dependent axonal degeneration and neuronal death [18, 19, 51]. It is possible that vincristine-driven ROS production impairs axonal calcium levels, leading to the activation of the SARM1-dependent axon degeneration program.

We also demonstrate that mdivi-1 reduces vincristine-induced axon degeneration by locally reducing the levels of ROS in the axon. Although it was initially discovered as an inhibitor of mitochondrial fission [32], mdivi-1 has since been shown to mitigate the production of ROS, possibly through the inhibition of complex I of the ETC [28]. In our study, we observed no evidence of mitochondrial fission after exposure to vincristine. Furthermore, knockdown of DRP1 did not reduce vincristine-induced axon degeneration, and treatment of DRP1-deficient neurons with mdivi-1 attenuated vincristine-induced axon degeneration. We therefore concluded that mdivi-1 protects axons from vincristine-induced degeneration by reducing ROS and not by inhibiting mitochondrial fission. The precise mechanism by which mdivi-1 reduces ROS is unclear. Two types of complex I inhibitors have been described: Class A compounds that inhibit complex I and increase ROS levels, and Class B that prevent the formation of ROS even in the presence of Class A inhibitors [52]. It is therefore possible that mdivi-1 behaves like a class B inhibitor, or through a different mechanism altogether.

A key methodological advance of our study was the use of microfluidic chambers to allow independent treatment of axons and cell bodies with vincristine and/or mdivi-1. This method allowed us to demonstrate that mdivi-1 acts locally in the axon to delay vincristine-induced axon degeneration. Furthermore, we observed that axon degeneration was more severe in locally treated axons than in neurons treated globally (Fig. 3E vs 3B), suggesting a possible adaptive mechanism by which the cell body signals to the axon to attenuate the injury response.

The rapid and scalable generation of iPSC-derived neurons using transcription factors provides an exciting and highly

relevant model in which to test the molecular mechanisms underlying CIPN and chemo brain. The  $i^3$ Neuron model has already been paired with CRISPR-interference (CRISPRi) technology [33, 53], highlighting its utility to identify new druggable pathways and develop novel therapeutic strategies for neurological side effects of chemotherapy. Perhaps most importantly, the human neuron platform helps circumvent potential issues of translatability. Most current knowledge on how chemotherapeutic agents cause axon degeneration derives from research performed in mouse cultured neurons, which may or may not translate well to human.

Using treatment-relevant levels of vincristine in human neurons, we have demonstrated that mitochondrial dysfunction and increase in ROS are early, axon-localized events in vincristine-induced axon degeneration. This degeneration can be pharmacologically mitigated by local treatment of axons with mdivi-1 and other antioxidant agents. Our study reveals that the mitigation of vincristine-induced ROS generation is an exciting novel potential therapeutic target for CIPN and chemo brain which should be further investigated. This work also advances our insight into how clinically relevant levels of vincristine causing mild axon degeneration can lead to the neurological side effects of chemotherapy.

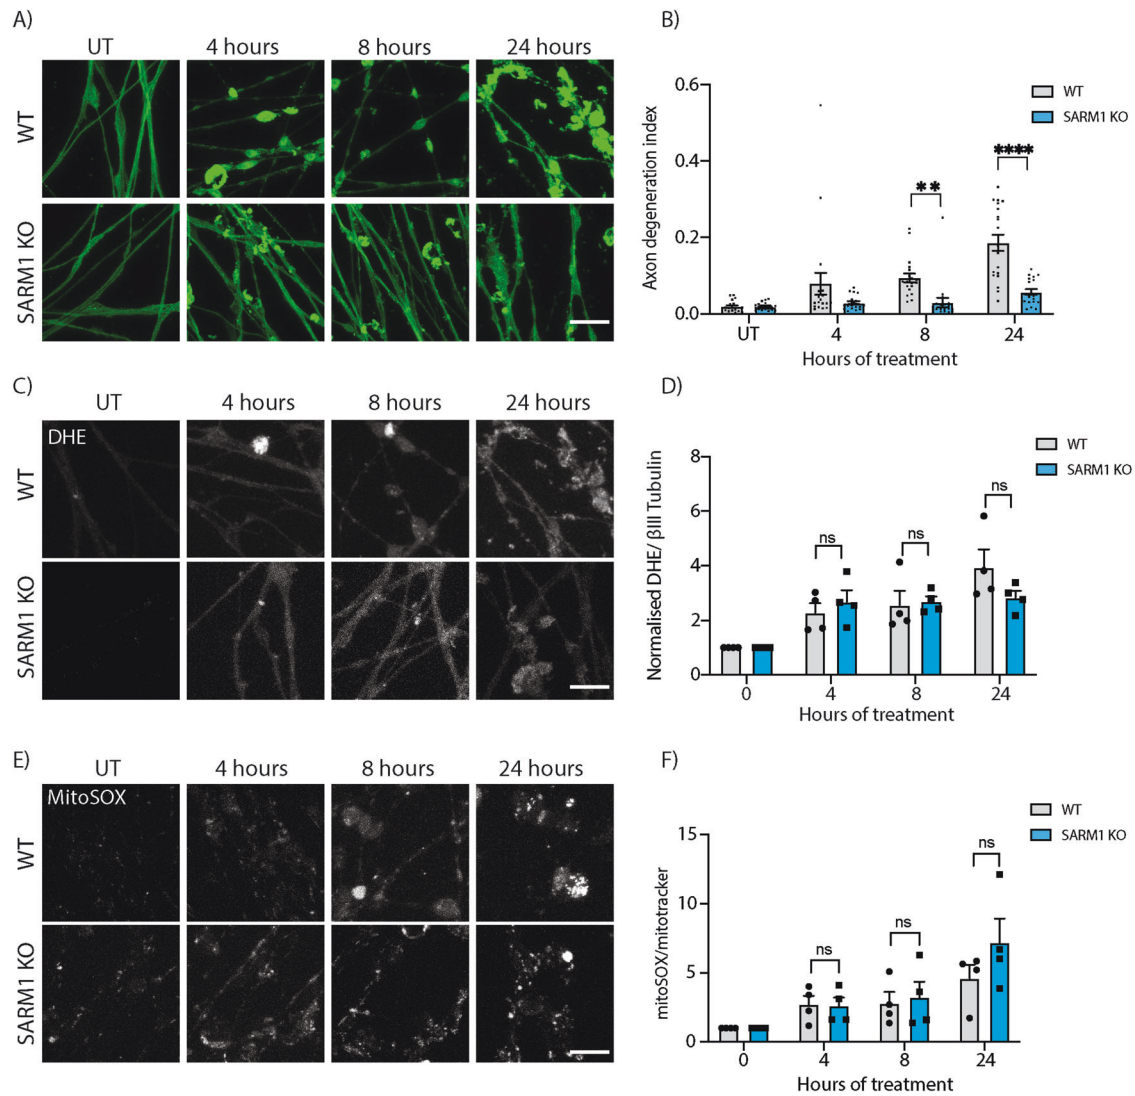

## METHODS

### Differentiation of $i^3$ Neurons

$i^3$ Neurons were differentiated as previously described [17]. Briefly,  $i^3$  iPSCs were dissociated using Accutase (Life Technologies, cat. no. A1110501). Cells were plated in Matrigel-coated (1:100 Corning) plates in neuronal induction media on day 0 (Knockout Dulbecco's modified Eagle's medium (DMEM)/F12 medium; Life Technologies Corporation, cat. no. 12660012), 1X N2 supplement (Life Technologies, cat. no. 17502048), 1x GlutaMAX (ThermoFisher Scientific, cat. no. 35050061), 1x MEM nonessential amino acids (NEAA) (ThermoFisher Scientific, cat. no. 11140050), 10  $\mu$ M ROCK inhibitor (Y-27632; Selleckchem, cat. no. S1049), and 2  $\mu$ g/ml doxycycline (Clontech, cat. no. 631311). Neuronal induction media was changed once a day for 2 more days. On day 3 of induction, cells were dissociated using Accutase and plated in dishes coated with poly-L-ornithine (PLO; 0.1 mg/ml; Sigma, cat. no. P3655-10MG). Cells were plated in neuronal maturation media (BrainPhys medium (STEMCELL Technologies, cat. no. 05790), 1x B27 Plus Supplement (ThermoFisher Scientific, cat. no. A3582801), 10 ng/ml BDNF (PeproTech, cat. no. 450-02), 10 ng/ml NT-3 (PeproTech, cat. no. 450-03), 1 mg/ml mouse laminin (Invitrogen, cat. no. 23017015), and 2  $\mu$ g/ml doxycycline). Half of the neuronal maturation media was removed and replenished with fresh media every 2–3 days.

### Axonal separation and vincristine treatment for mass spectrometry

On day 3 of differentiation, 2 million cells were plated into Falcon® Permeable Support for 6-well plate with 1.0  $\mu$ m transparent PET membrane (Boyden chambers, cat. No. 353102) in 2 mL of neuronal maturation media. Half media changes were performed every 3–4 days. On day 14 of differentiation, the axonal compartment of the chamber was treated with

**Fig. 6 SARM1 knockout prevents axon degeneration and does not prevent axonal and mitochondrial ROS production after vincristine treatment.** **A** Representative images of 5 nM vincristine-treated WT and SARM1 KO  $i^3$ Neuron axons. Immunostaining for  $\beta$ III tubulin (green). Scale bar = 20  $\mu$ m. **B** Axonal degeneration index of the experiments shown in (A). Vincristine treated WT and SARM1 KO  $i^3$ Neuron axons. Results are represented as mean  $\pm$  SEM.  $N = 4$  independent differentiations, 5 images per differentiation. Two-way ANOVA, Bonferroni correction ( $p < 0.01$  \*\*,  $p < 0.0001$  \*\*\*\*). **C** Representative images of 5 nM vincristine-treated WT and SARM1 KO neurons. Staining with DHE (white). Scale bar = 20  $\mu$ m. **D** Quantification of DHE fluorescence in 5 nM vincristine WT and SARM1 KO  $i^3$ Neuron axons shown in (C). Results normalized to untreated axons. Results are represented as mean  $\pm$  SEM.  $N = 4$  independent differentiations, 5–10 images per differentiation. Two-way ANOVA, Bonferroni correction (ns not significant). **E** Representative images of 5 nM vincristine-treated WT and SARM1 KO  $i^3$ Neuron axons ROS quantification. Staining with mitoSOX (white). Scale bar = 20  $\mu$ m. **F** Quantification of mitoSOX fluorescence in 5 nM vincristine WT and SARM1 KO  $i^3$ Neuron axons shown in (E). Results normalized to untreated axons. Results are represented as mean  $\pm$  SEM.  $N = 4$  independent differentiations, 5–10 images per differentiation. Two-way ANOVA, Bonferroni correction (ns not significant).

5 nM vincristine or DMSO (Sigma, cat. no. 276855) for 4 h. Axonal and cell body fractions were harvested in ice cold RIPA buffer (Invitrogen, cat. no. 89901) supplemented with protease inhibitors (Sigma, 11836153001). Protein concentrations were calculated using a BCA assay (ThermoFisher, cat. No. 23225). 50  $\mu$ g of protein was boiled in loading buffer (Invitrogen cat. no. NP0008) and loaded into a 7.5% Mini-PROTEAN<sup>®</sup> TGX<sup>™</sup> (BioRad, cat. No. 4561023) for 5 min until all protein moved into the gel. Bands were subsequently cut and subjected to mass spectrometry.

#### Immunofluorescence, vincristine, and mdivi-1, Glutathione and Mitoquinone (MitoQ) treatments

For immunofluorescent staining of  $i^3$ Neuron axons, cells were plated on a PLO-coated 8-well plate (Ibidi, cat. No. 80827) by adding a 10  $\mu$ l drop of neuronal maturation media containing ~100,000 cells to the center of each

well. Cells were placed in the cell culture incubator for 20 min to allow for attachment to the center of the well. 200  $\mu$ l of neuronal maturation media was then added to the well. For immunofluorescent staining of whole neurons, cells were plated on PLO-coated 96 well plates (PerkinElmer cat. No. 6055300) with 50,000 cells/well. On day 10 or 11 of neuronal differentiation, cells were treated with 5 nM vincristine, 50  $\mu$ M mdivi-1 (Sigma, M1099), 5mM L-Glutathione (reduced) (Sigma, G-4251), and 5  $\mu$ M Mitoquinone (MitoQ) mesylate (Selleckchem, S8978). After treatment, cells were fixed in cold 4% PFA for 5–10 min. Cells were permeabilized using 0.1% Triton X-100 in PBS for 5 min and blocked in 5% normal donkey serum (NDS) in PBS at room temperature for 1 h. Cells were immunostained with anti-beta-3 Tubulin (Invitrogen, cat. no. 2G10-TB3, 1:500) in 2.5% NDS overnight at 4  $^{\circ}$ C. Cells were washed three times with PBS and stained with the Alexa Fluor 595 (ThermoFisher cat. no. A-21203) secondary antibody at a concentration of 1:500 in 2.5% NDS for 1 h at

**Fig. 7 Proposed model for vincristine-induced axon degeneration in human neurons.** Low doses of vincristine (5 nM) induce axonal degeneration in  $i^3$ Neurons within 24 h of treatment. Preceding axonal degeneration, vincristine induces mitochondrial dysfunction by reducing basal respiration rates of  $i^3$ Neurons, and inducing both total axonal (DHE) and mitochondria (MitoSOX) ROS production upstream of SARM1 activation. Concurrent treatment of vincristine and mdivi-1 reduces the local production of ROS in axons. Treatment with antioxidants GSH and mitoquinone also reduces axonal ROS. Mdivi-1 subsequently delays vincristine-induced axonal degeneration in both whole cell cultures and axons only, in a DRP1-independent manner.

room temperature. Cells were washed three times with PBS and DAPI was used as a nuclear counterstain.

### DHE and ROS quantification

Cells were plated in an 8-well dish. On Day 10 or 11 of differentiation, cells were treated with 5 nM vincristine, or a cocktail of 5 nM vincristine and 50  $\mu$ M mdivi-1. Treatments were added 24, 8, and 4 h prior to staining with both DHE and mitoSOX. In this way, all conditions were treated with the same stock of DHE and MitoSOX to avoid differences in solution preparation. For quantification of total ROS levels, cells were treated with DHE (ThermoFisher, cat. no. D11347, 1:1000, Excitation: 508 nm Emission: 575 nm) for 30 min at 37 °C and fixed in cold 4% PFA for 5–10 min. Cells were immunostained with anti-beta-3 Tubulin as described above. For quantification, 5–8 images of the axons were taken using a Zeiss 800 LSM Scanning Microscope. Fluorescent intensity of DHE was quantified and FIJI imaging analysis software and normalized to the area of tubulin (total axonal area) in a blinded manner.

For mitochondrial ROS quantification, cells were treated with MitoTracker Green (ThermoFisher, cat. No. M7514, 1:1000, excitation: 490 nm emission: 516 nm) and MitoSOX<sup>™</sup> Red Mitochondrial (ThermoFisher, cat. No. M36008, 1:1000, excitation: 510 nm emission: 602 nm) for 30 min at 37 °C. Cells were washed twice in PBS and fresh media was added. For quantification, live imaging was performed at 37 °C, 5% CO<sub>2</sub>. 5–8 images of the axons were taken using a Zeiss LSM 800 confocal. Fluorescent intensity of MitoSOX<sup>™</sup> Red was quantified using FIJI imaging analysis software and normalized to the area of MitoTracker Green (mitochondrial area) in a blinded manner.

### Mass spectrometry

In-gel samples (~ 20  $\mu$ g per sample) were reduced using 10 mM Tris(2-carboxyethyl) phosphine hydrochloride at room temperature for 1 h and alkylated with 10 mM N-Ethylmaleimide for 10 min. Samples were digested with trypsin (Promega) with a trypsin:sample ratio of 1:20 (w/w) at 37 °C for 18 h. Tryptic digests were extracted from the gel and cleaned with an Oasis HLB  $\mu$ Elution plate (Waters). Peptides were separated on an ES802A column. Mobile phase B (98% ACN, 1.9% H<sub>2</sub>O, 0.1% formic acid) amount was increased from 3% to 20% over 83 min. Mobile phase A composition is 98% H<sub>2</sub>O, 1.9% ACN, 0.1% formic acid. LC-MS/MS data were acquired in data-dependent mode. The MS1 scans were performed in orbitrap with a resolution of 120 K, a mass range of 400–1500 m/z, and an AGC target of  $4 \times 10^5$ . The quadrupole isolation window is 1.6 m/z. The precursor ion intensity threshold to trigger the MS/MS scan was set at  $1 \times 10^4$ . MS2 scans were conducted in ion trap. Peptides were fragmented with CID method and the collision energy was fixed at 30%. MS1 scan was performed every 3 s. As many MS2 scans were acquired within the 3 s cycle.

Proteome Discoverer software version 2.4 (ThermoFisher) was used for protein identification and quantitation. Raw data were searched against Sprot Human database. Up to 2 missed cleavages were allowed for trypsin digestion. NEM on cysteines was set as fixed modification. Mass tolerances for MS1 and MS2 scans were set to 10 ppm and 0.6 Da, respectively. Percolator was used for PSM validation. The search results were filtered by a false discovery rate of 1% at the protein level. Protein abundance values were calculated for all proteins identified by summing the abundance of unique peptides matched to that protein. Protein ratios were calculated by comparing the protein abundances between two conditions with normalization. Adjusted p-values were calculated with the ANOVA method.

### Seahorse analysis

For Seahorse analysis, 50,000 cells per well were plated after 3 days of induction in a specialized Seahorse analyzer 96-well plate (Agilent, cat. no. 103774-100). 10–12 day old  $i^3$ Neurons were treated with 5 nM vincristine. Oligomycin (2  $\mu$ M), FCCP (1  $\mu$ M) and rotenone/antimycin A (500 nM) were added as shown in Fig. 2A. Cells were washed in PBS once and incubated in a hypoxic chamber following the manufacturer's procedure. Seahorse analysis was performed using a Seahorse XFe96 Analyzer (Agilent). The average value for three wells was used for analysis.

### Western blotting

10–14 day old  $i^3$ Neurons were harvested in ice cold RIPA buffer (Invitrogen, cat. no. 89901) supplemented with protease inhibitors (Sigma, 11836153001) and PhosStop (Sigma, cat. no. 4906845001). Protein concentrations were calculated using a BCA assay (ThermoFisher, cat. no. 23225). 10–20  $\mu$ g of total protein lysate was loaded into a 4–20% Mini-PROTEAN<sup>®</sup> TGX<sup>™</sup> Precast Protein Gels (Biorad, cat. no. 4561095). Gels were transferred into PVDF membranes and blocked for 1 h at room temperature in 5% BSA. Membranes were incubated with the primary antibody (primary antibodies, catalog numbers and concentrations listed below) in 2.5% BSA solution in a cold room, rocking, overnight. Membranes were washed 3 times with PBS 0.1% Tween solution. Secondary antibody (goat anti-rabbit HRP and IRDye<sup>®</sup> 680RD Goat anti-Mouse IgG) was incubated for 1 h at room temperature at a concentration of 1:8000 in 2.5% BSA solution. Membranes were washed 3 times with PBS 0.1% Tween solution prior to developing. Western blots were developed using Clarity Western ECL Substrate (Biorad, cat. no. 1705061) or fluorescence and imaged using a ChemiDoc MP Imaging system (Biorad). Band intensity was quantified using FIJI imaging analysis software. The following antibodies were used at the concentrations stated: anti-DRP1 (Santa Cruz Biotechnology, cat. no. sc-101270, 1:1000), anti-pDRP1 S616 (CST, cat. no. 3455 S, 1:1000), anti- $\beta$  Actin (Sigma, cat. no. A1978, 1:5000), anti-Lamin A (Sigma, cat. no. L1293, 1:1000), anti-NDUFA12 (Santa Cruz Biotechnology, cat. no. SC-398869, 1:500), anti-NDUFB9 (Abcam, cat. no. AB-192617, 1:2000), anti-Cytochrome C (Biolegend, cat. no. 612302 1:1000). Full uncropped Western blots are provided as a supplement (Original Data Files).

### Axon degeneration index experiment and quantification

On day 3 of differentiation,  $i^3$ Neurons were dissociated into single cells with Accutase, and plated in Ibidi 8-well  $\mu$ -Slides (Ibidi, Cat. No. 80826). 50,000 cells were plated in a 5  $\mu$ L drop of neuronal maturation media in the middle of each well for the axons to grow out from the center. Slides were incubated for 20 min at 37 °C to allow cells to attach, and 200  $\mu$ L of neuronal maturation media was then added to each well. Cells were fed with half-media changes every two days until the day of the experiment. Two slides were used for each experiment. On Day 10 or 11 of differentiation, 5 nM vincristine or a cocktail of 5 nM vincristine and 50  $\mu$ M mdivi-1 was prepared in neuronal maturation media and added to 6 wells of an 8-well slide. The remaining two wells were fixed at the start of the experiment for the untreated timepoint. Two wells of each slide were fixed at 4 h, 8 h, and 24 h after treatment using 4% cold PFA for 5–10 min, then washed three times with PBS. The slides were subsequently blinded for processing and imaging. Cells were immunostained with  $\beta$ III-Tubulin primary antibody, AlexaFluor 594 (ThermoFisher, cat. no. A-21203) secondary antibody, and DAPI as described above. Images were acquired on a Zeiss LSM 800 laser-scanning confocal microscope. Five images of axons from two technical replicate wells were taken, for a total of ten images per timepoint per treatment, for three biological replicates. Images were taken at the distal-most end of the neurons to ensure axons, and not dendrites, were being captured. An axon degeneration index for each image was calculated as follows: 8-bit maximum intensity projections were

binarized and thresholded [22] in the FIJI imaging analysis software. The same threshold was used for each image analyzed across biological replicates. The total number of black pixels was measured to be the total axonal area. The degenerated area was measured to be the total area of particles whose pixel circularity was 0.2–1.00. The axon degeneration index (ADI) is calculated as the degenerated area divided by the total axonal area (Supplementary Fig. 1).

### Generation and validation of DRP1 knockdown

Control and DRP1 gRNA were cloned into a plasmid containing a U6 promoter using BstXI and BlnI restriction enzymes (NEB) (gifted by Dr. Michael Ward, NINDS). Control gRNA sequence: GGA CTA AGC GCA AGC ACC TA. DNMT1L gRNA sequence: GGG AGG AAG GAG GCG AA CTG. Constructs were verified by Sanger Sequencing and packaged into lentivirus for transduction of iPSCs as follows. In one well of a 6-well plate, 1 million Lenti-X HEK293T cells (Takara Bio, cat. no. 632180) were seeded in 2 mL DMEM (Gibco, cat. no. 11995065) supplemented with 10% FBS (Gibco, cat. no. 10437028). The next day, a transfection mix was prepared containing 1 µg DNMT1L or Control gRNA-containing plasmid, 3 µg of third generation packaging mix (1:1:1 mix of three plasmids), 12 µL Lipofectamine 3000 Reagent (ThermoFisher, cat. no. L3000008), and 200 µL Opti-MEM 1 Reduced Serum Medium (GIBCO, cat. no. 31985070). The mix was vortexed, spun down briefly, incubated at room temperature for 20 min, then added dropwise to the HEK293T cells and gently swirled to mix. The next day, the media was replaced with 3 ml fresh 10% FBS DMEM supplemented with 1:500 ViralBoost (Alstem, Cat. No. VB100). After two days of incubation, the media was collected into a 15 ml Falcon tube, supplemented with 1 ml Lenti-X Concentrator (Takara Bio; Cat. No. 631231), mixed thoroughly, and stored at 4 °C for 48 h. The supernatant was then spun down at 4 °C for 45 min at 1500 x g. The supernatant was aspirated, and the pellet was resuspended in 300 µL of PBS.

CRISPRi-<sup>3</sup> iPSCs containing a CAG promoter-driven dCas9-BFP-KRAB cassette inserted into the CLYBL safe harbor locus were the kind gift of Dr. Michael Ward [33]. 500,000 cells were seeded in one well of a Matrigel-coated 6-well plate and transduced with 100 µL of DNMT1L, or control sgRNA vector lentivirus in 2 ml mTESR Plus Basal Media with ROCK inhibitor. The next day, fresh media was added containing 1 µg/ml puromycin (Gibco; cat. no. A1113803). Transduced CRISPRi-<sup>3</sup>N iPSCs were subsequently passaged twice with puromycin until all cells were visibly expressing BFP. One well of a 60–80% confluent 12-well was harvested with 700 µL QIAzol Lysis Reagent (Qiagen; Cat. No. 79306) for subsequent RNA extraction with RNeasy Mini Kit (Qiagen; Cat. No. 74104) and cDNA synthesis (random hexamers method) with SuperScript III First-Strand Synthesis System (Invitrogen; Cat. No. 18080051) with an input of 1 µg of RNA. Samples were prepared for quantitative real-time PCR in technical duplicates. qPCR was performed with SYBR Green Quantitative RT-qPCR Kit (Sigma-Aldrich; Cat. No. QR0100) using GAPDH as a housekeeping gene, with the CFX Connect Real-Time PCR Detection System (BioRad; Cat. No. 1855201). The following primers were used. GAPDH RNA Fwd: AATGGCAGCCGTTAG-GAA GAPDH RNA Rev: GCGCCAATACGACCAAATC DNMT1L RNA Fwd: GTTGATCCACTTGGTGGCT DNMT1L RNA Rev: GCCGCTCACCAGTAACTA. Expression fold changes were calculated using the  $\Delta\Delta C_t$  method.

### Annexin V staining

<sup>3</sup>Neurons were plated in the center of 8-well slides as described above for axons to grow outwards. At 10–14 days old, <sup>3</sup>Neurons were treated with 5 nM vincristine or 5 nM vincristine with 50 µM mdvi-1. 23 h after treatment, the cells were incubated with 1:1000 Annexin V, AlexaFluor<sup>TM</sup> 488 conjugate (Invitrogen; Cat. No. A13201) for 1 h at 37 °C. Images were acquired 24 h after treatment, in a stage top 5% CO<sub>2</sub> and 37 °C temperature-controlled incubator on a Zeiss LSM 800 laser scanning confocal microscope.

### Generation of SARM1 KO iPSCs

WT iPSCs were transfected with two gRNAs targeting exon 2 of the SARM1 gene gRNA1: AATGCGGCCACGCGGTCT and gRNA2: CTGTATTG GTGCCGCCGCA and a Cas9-GFP expressing constructs. iPSCs were allowed to grow for two days, then colonies were dissociated to make single cells using Accutase for 10 min at 37 °C and a serial dilution was performed in two 6-well plates in mTESR Plus Basal Media with ROCK inhibitor. iPSCs were allowed to grow until single colonies were visible, hand-picked using a P1000 pipette, and an individual colony was transferred to a well of a 24-well plate. Once confluent, 10% of the cells were used for passaging and DNA was extracted on the remaining 90% of the cells using a Qiagen DNA extraction

kit (Qiagen; Cat. No. 69504). Clones were screened by PCR and sequencing confirmed the deletion of a 161 bp fragment in the SARM1 KO iPSCs.

### Statistical analysis

All quantification of microscopy images was performed blinded. Statistical analyses were performed using GraphPad Prism 9. Gene ontology analysis was performed in R version 4.0.3 (2020-10-10). String analysis was performed with <https://string-db.org> version 11.5.

### DATA AVAILABILITY

Proteomics raw data, peak list and search results have been deposited to the ProteomeXchange Consortium with the dataset identifier: [PXD045536](https://doi.org/10.26434/chemrxiv-2023-pxd04).

## ACKNOWLEDGEMENTS

We would like to acknowledge the NICHD microscopy facility, with special thanks to Dr. Vincent Schram. We would also like to thank Dr. Yan Li from the NINDS mass spectrometry facility for help generating the proteomics data, Dr. Nunziata Maio for helping with the Seahorse experiments and Dr. Alexander Chesler and Eliza Lloyd for their helpful comments on the manuscript. Finally, we would like to thank Dr. Michael E. Ward and his team at NINDS, the University of California, San Francisco and the Gladstone Institute for sharing the i3Neurons. This work was funded by the Intramural Research Program at the National Institutes of Health (IRP-NIH) through NICHD (ZIA-HD008966 to CELP) and the ALS association (ALSA) Milton Safenowitz Postdoctoral Fellowship (JGD).

## AUTHOR CONTRIBUTIONS

Experimental design and conceptualization: JGD, ALS, CELP. Execution and analysis of experiments: JGD, ALS, MN. Writing: JGD, ALS, CELP.

## FUNDING

Open Access funding provided by the National Institutes of Health (NIH).

## COMPETING INTERESTS

The authors declare no competing interests.
