Optimization of the electron transport layer in quantum dot light-emitting devices

Gary Zaiats¹, Shingo Ikeda^{1,2} and Prashant V. Kamat¹

Abstract

Quantum dot light-emitting devices have emerged as an important technology for display applications. Their emission is a result of recombination between positive and negative charge carriers that are transported through the hole and electron conductive layers, respectively. The selection of electron or hole transport materials in these devices not only demands the alignment of energy levels between the layers but also balances the flow of electrons and holes toward the recombination sites. In this work, we examine a method for device optimization through control of the charge carrier kinetics. We employ impedance spectroscopy to examine the mobility of charge carriers through each of the layers. The derived mobility values provide a path to estimate the transition time of each charge carrier toward the emitting layer. We suggest that an optimal device structure can be obtained when the transition times of both charge carriers toward the active layer are similar. Finally, we examine our hypothesis by focusing on thickness optimization of the electron transport layer.

Introduction

Semiconducting quantum dots (QDs) carry tunable optical properties and good stability and can be synthesized following scalable colloidal synthesis routes. They have attracted much interest in the development of quantum dot light-emitting devices (QLEDs)^{1–6}. In a typical QLED, the nanoparticles emit light as a result of radiative recombination between positive and negative charge carriers. The emitting layer of the nanoparticles is termed the active layer. The charges are injected from the anode and cathode to the active layer with adjacent electron and hole transport layers (ETL and HTL, respectively). The device performance is directly related to the light-emission efficiency of the materials selected for the active layer of the device architecture. Among different types of light-emitting nanoparticles, CdSe and CdS QDs (II–VI elements) exhibit high efficiency and stability. Their high photoluminescence (90%) implies the high

efficiency of radiative electron-hole recombination in these materials. This recombination has a significant role in electroluminescent devices. Recently, published works exhibit an external quantum efficiency of ~20% for CdSe/CdS QLED devices^{7–9}. However, the heavy metal ion cadmium (Cd) raises health concerns and requires corresponding environmental regulations^{9,10}. For example, the EU directive specifies a maximum limit of 100 ppm for the Cd concentration in electronic devices. Hence, it is of high interest to unveil alternative materials and explore the effect of the device architecture on QLED performance. Multinary compounds composed of Cu-In-S, Ag-In-S, and their alloys with ZnS are promising candidates for these applications. These materials offer structural and compositional flexibility, which can be utilized to control their optical properties. Moreover, some works exhibit 60–90% photoluminescence efficiency of these nanoparticles^{11–13}. The efficiency of charge transport between layers depends on the alignment of energy levels within a device. It is generally accepted that material selection for the optimal device should give precedence to charge movement toward the active layer, where the charges then recombine^{14–17}.

Recent works have suggested that not only does energy alignment (i.e., thermodynamics) have a role but also the rates of charge carrier transfer toward the active layer (i.e., kinetics)¹⁸. The time that is required for charge transfer from the anode or cathode toward the active layer depends on the charge mobility, concentration of the charge carriers, and thickness of the HTL or ETL. If the hole transport time through the HTL differs from the transport time of electrons through the ETL, accumulation of one type of charge carrier at the interfaces can result in a loss of emission efficiency and can induce degradation. Thus, the optimization of QLEDs requires the development of experimental approaches that will esteem to the abovementioned thermodynamic and kinetic parameters.

Impedance spectroscopy is a well-established experimental method for elucidating the charge transfer kinetics in materials. During impedance analysis, the resistance and capacitance response to alternating voltage as a function of frequency is recorded. Subsequently, the data are fitted to the analytical models, representing equivalent electrical circuits composed of elemental components, such as resistors, capacitors, and inductors. The fitting parameters shed light on the kinetics of charge transfer phenomena in electronic materials or devices.

In this work, we employ impedance spectroscopy to evaluate the apparent charge mobility of electrons and holes in the ETL and HTL, respectively. Based on these values, we estimate the optimal thickness of the ETL for a given thickness of the HTL. Finally, we show the agreement between our model and the efficiency trend of experimentally examined devices.

Results and discussion

QD characterization

The emission properties of QLEDs are controlled by the optical properties of the nanoparticles. The absorbance combined with the electron affinity determines the alignment of energy levels within a device and the corresponding electroluminescence activation conditions. The photoluminescence spectra complete the picture by revealing radiative electron-hole recombination paths^{19–22}. Figure 1a shows the absorbance and emission spectra of Cu-In-Zn-S (CIZS) nanoparticles in toluene solution. The broad excitonic transition and large Stokes shift are typical for multinary nanoparticles. They originate from donor–acceptor interactions as a result of crystalline and surface defects^{21–26}. In spin-coated nanoparticle films (Fig. 1b, curve b), the distance between the nanoparticles is reduced. Thus, the probability for energy transfer from high-energy transitions to narrower transitions increases, and the corresponding emission spectrum is redshifted (Fig. 1b, the emission is redshifted from curve (a) toward

Fig. 1 Optical properties of CIZS nanoparticles. **a** Absorbance and photoluminescence spectra of CIZS nanoparticles. curve (b))^{27–30}. The application of an external voltage further redshifts the emission (from 685 to 715 nm), implying an enhancement of the interparticle interactions (Figure S1(A)). However, as the voltage is increased, opposite blueshifting (Figure S1(B)) can be observed, as the nanoparticles with wider donor–acceptor energy transitions (a consequence of the shape and size of the composition distribution) are activated (curves c–h).

Layer characterization

An appropriate alignment of energy levels between different layers of QLEDs is often set as one of the criteria in QLED design engineering. Figure 2a exhibits the energy levels of different materials in our devices. The

characteristic values of the valence and conduction edges were reported by others^{16,18,30–36}. In nanoparticles, the valence and conduction edges are size- and composition-dependent. However, the variations remain within tenths of electron volts (eV)³⁷. Hence, these values represent the typical range for reference purposes only. The materials are selected in a manner that prioritizes electron-hole recombination in the QD layer³⁸. Fig. 2b shows the cross section of a typical device that was fabricated in this work.

Although the energy diagram (Fig. 2a) provides an important guideline for the selection of materials, it does not offer sufficient information on the controlled thickness of each individual layer. Optimization of the device structure requires balancing the charge carrier concentrations and their mobility in both the ETL and HTL. In other words, the concentration of the holes in the active layer needs to be similar to the concentration of the electrons to maximize charge carrier recombination¹⁸. Thus, we need to achieve the transition time of the electrons from the aluminum contact to the CIZS active layer, which is the same as the transition time of the holes from the ITO to the CIZS layer. By controlling the thicknesses of the ETL and HTL, it should be possible to maximize the availability of electrons and holes at the CIZS interface. This parameter of modulating the flow of charge carriers becomes important in the design and optimization of QLEDs.

Impedance spectroscopy monitors the system response to alternating current modulation. These data can be used to shed light on the charge transfer and recombination processes^{39–42}. We employed impedance spectroscopy to probe the apparent charge mobility in each of the layers, viz., ZnO, TPD, and CIZS QDs. A film of the examined material with varying thickness was deposited between gold electrodes (cross-section is shown in Fig. 3a). The response of the system under different frequencies of alternating perturbation can be presented using a Nyquist plot (Fig. 3b). The maximal value of the imaginary component of the impedance is obtained at a frequency corresponding to the characteristic response time of the sample (τ). The value of τ is calculated as a product of the resistivity (R_1) and capacity (C_1) of the represented electrical circuit (Fig. 3c)²⁵. This characteristic time (τ) is related to the bias voltage (V_b), charge drift mobility (μ), and thickness (d) of the sample through Eq. (1):^{42–46}

$$\tau = \frac{d^2}{\mu \cdot V_b} \quad (1)$$

Finally, the mobility of the charge carriers can be calculated from the slope of the curve, which describes the dependence of τ on the reciprocal voltage ($1/V_b$) (Fig. 3d).

Table 1 Charge mobility values determined from impedance spectroscopy analysis.

Material	μ [$\text{cm}^2/(\text{V}\cdot\text{s})$] current work	μ [$\text{cm}^2/(\text{V}\cdot\text{s})$] previous reports
ZnO	1.7×10^{-3}	7.2×10^{-4} – 4.8×10^{-3} Ref. ³⁵
CIZS QDs	1.7×10^{-4}	NA
TPD	2.1×10^{-3}	2×10^{-3} – 3×10^{-3} Ref. ^{36,51}
PEDOT	1.2×10^{-2}	8×10^{-3} – 1×10^{-2} Ref. ⁵²

The linear dependence of τ on the bias voltage confirms the validity of Eq. (1). From the slopes of the linear plots (Fig. 3d), we can obtain a ratio of $\frac{d^2}{\mu}$. We further determine the thickness of each layer by scanning electron microscopy and focused ion beam cross-sectional analysis (Figure S2). This allows us to calculate the charge mobility of each of the layers that are part of the light-emitting device. It is difficult to compare the charge mobility in CIZS QDs owing to the dependence on the exact composition, crystalline structure, size, and type of ligands^{47,48}. However, for other layers, we find good agreement with previous reports (Table 1). The mobilities of different layers vary between 1.7×10^{-4} and $1.2 \times 10^{-2} \text{ cm}^2/(\text{V}\cdot\text{s})$. This varying degree of mobility indirectly prescribes the optimal thickness of each layer. To

optimize the device thickness, we employ an HTL (PEDOT + TPD) thickness of 45 ± 5 nm and vary the thickness of the ETL (ZnO) layer.

Device optimization

The power conversion efficiency (PCE) of light-emitting devices is calculated as the ratio of the optical power generated from an LED to the electrical input power. The input power is a product of the operating voltage and current. The emission power can be calculated from the photocurrent of a calibrated photodiode placed close to the QD LED assuming Lambertian emission ($\eta = \frac{P_{out}}{P_{in}} = \frac{P_{out}}{IV}$)^{30,49}. Figure 4 shows the power conversion efficiency as a function of the ZnO layer thickness. We calculate the thickness of the ZnO layer such that it promises equal transition times for electrons (through ZnO) and holes (through PEDOT/TPD) ($\tau_e(\text{ZnO}) = \tau_h$). For the calculation, we use the mobility values from Table 1 and the measured thickness of the HTL (30–40 nm). Owing to the thickness variation of the HTL, the optimal thickness range is marked by a shadowed zone (rather than by a line) in Fig. 4. Subsequently, we measure the efficiency of the devices as a function of the ZnO layer thickness, between 15 and 460 nm. Initially, increasing the thickness of the ZnO layer from 15 to 60 nm improves the balance between the positive and negative charge carriers by increasing the transition time of electrons. Accordingly, the PCE of the devices increases six times from 0.1% to ~0.6%. The characteristic PCE for multinary nanoparticle light-emitting devices reported by others is ~1%^{30,31,50}. A further increase in ZnO thickness increases the transition length and time of the electrons. This deteriorates the balance of charge carriers with the active layer, and the PCE is reduced. This observation leads to an estimation where the optimal thickness of the ZnO layer in this device is ~80 nm. Obviously, there is an agreement between the estimated optimal range and the experimental results. A more-accurate approximation requires estimating the dependence of the emission efficiency

on the depth of the radiative recombination in the active layer.

In this work, we showed how impedance spectroscopy analysis can be employed for the measurement of the charge transport time through hole or electron transport layers. While keeping the thicknesses of the hole and active layers constant, we could estimate the optimal thickness of the electron transport layer. Our experimental results show that the maximal emission efficiency is obtained when the negative and positive charge carrier transition times are equal. Further work is required to estimate the contribution of the active layer thickness and emissions from different depths of this layer.

Conclusions

The outstanding optical properties of colloidal QDs make them good candidates for light-emitting devices. A typical QD LED is composed of a light-emitting layer between the electron and hole conductors. The efficiency of the devices is a result of the nanoparticle emission efficiency and the device architecture. Commonly used interlayer energy alignment (a thermodynamic consideration) provides a guideline for efficient charge transfer. However, it does not provide any information regarding the film thickness, which affects the transition time of the charge carriers. Unequal transition times of positive and negative charge carriers lead to charging phenomena and subsequently nonradiative decay processes. Hence, an unequal transition time deteriorates the device efficiency. Impedance spectroscopy can be employed to obtain essential information on the charge mobility in each of the layers. Based on these data, the optimal thickness of each of the layers can be evaluated.
