ARTICLE OPEN Electrically and magnetically switchable nonlinear photocurrent in *PT*-symmetric magnetic topological quantum materials

Hua Wang¹ and Xiaofeng Qian ^[D][™]

Nonlinear photocurrent in time-reversal invariant noncentrosymmetric systems such as ferroelectric semimetals sparked tremendous interest of utilizing nonlinear optics to characterize condensed matter with exotic phases. Here we provide a microscopic theory of two types of second-order nonlinear direct photocurrents, magnetic shift photocurrent (MSC) and magnetic injection photocurrent (MIC), as the counterparts of normal shift current (NSC) and normal injection current (NIC) in time-reversal symmetry and inversion symmetry broken systems. We show that MSC is mainly governed by shift vector and interband Berry curvature, and MIC is dominated by absorption strength and asymmetry of the group velocity difference at time-reversed $\pm k$ points. Taking \mathcal{PT} -symmetric magnetic topological quantum material bilayer antiferromagnetic (AFM) MnBi₂Te₄ as an example, we predict the presence of large MIC in the terahertz (THz) frequency regime which can be switched between two AFM states with time-reversed spin orderings upon magnetic transition. In addition, external electric field breaks \mathcal{PT} symmetry and enables large NSC response in bilayer AFM MnBi₂Te₄, which can be switched by external electric field. Remarkably, both MIC and NSC are highly tunable under varying electric field due to the field-induced large Rashba and Zeeman splitting, resulting in large nonlinear photocurrent response down to a few THz regime, suggesting bilayer AFM-z MnBi₂Te₄ as a tunable platform with rich THz and magneto-optoelectronic applications. Our results reveal that nonlinear photocurrent responses governed by NSC, NIC, MSC, and MIC provide a powerful tool for deciphering magnetic structures and interactions which could be particularly fruitful for probing and understanding magnetic topological quantum materials.

INTRODUCTION

Magnetic topological quantum materials have attracted a lot of interest as the interplay between magnetic ordering and topology may enable exotic topological quantum states. For example, antiferromagnetic (AFM) topological insulator¹ can host topological axion states with nonzero quantized Chern-Simons magnetoelectric coupling², which was recently predicted in the class of layered MnBi₂Te₄ materials^{3–5}. The nontrivial topological surface states have been experimentally verified in MnBi₂Te₄^{6–8}. While various experiments have been carried out to study their electronic structure and transport properties, optical probes, especially nonlinear optical spectroscopy, may provide a rich set of alternative tools to probe their topological nature and understand the inherent electronic structure in these exotic quantum materials.

Nonlinear optical responses play a key role in understanding the symmetry, ordering, and topology. Materials with strong nonlinear responses are particularly valuable for ultrafast non-linear optics⁹, efficient generation of entangled photon pairs^{10,11}, and phase-matching free nonlinear optics^{12,13} using 2D materials. Recently, nonlinear photocurrent responses including normal shift current (NSC)^{14–18}, normal injection current (NIC)^{17–21}, and Berry curvature dipole-induced current^{22–24} have been observed in time-reversal invariant noncentrosymmetric systems. Recently, nonlinear shift current was proposed in centrosymmetric crystals via geometric photon-drag effect²⁵. In particular, Berry curvature dipole induced photocurrent is closely coupled with ferroelectric orders, offering a unique approach to detect low-energy

ferroelectric transition. This was recently theoretically proposed and experimentally verified in ferroelectric few-layer WTe₂ semimetal, opening avenues to the development of nonlinear quantum memory^{24,26}. Compared to few-layer WTe₂, layered MnBi₂Te₄ is magnetic with tunable nontrivial topology, which may lead to magnetically and electrically controlled large nonlinear photocurrent responses. The effect of magnetic ordering and intrinsic topology on nonlinear responses in MnBi₂Te₄, however, has been largely underexplored.

Here we provide a microscopic theory of two types of secondorder nonlinear current responses, namely magnetic injection current (MIC) and magnetic shift current (MSC), which are the counter part of the well-known NIC and NSC in time-reversal invariant noncentrosymmetric system. Both MIC and MSC can be induced in \mathcal{PT} -symmetric systems with space inversion (\mathcal{P}) and time reversal (\mathcal{T}) being individually broken. We take magnetic topological quantum material bilayer AFM MnBi₂Te₄ as an example of \mathcal{PT} -symmetric system and predict that MIC can be switched in time-reversal breaking MnBi₂Te₄ upon magnetic transition, namely magnetically switchable nonlinear photocurrent. In addition, vertical electric field breaks \mathcal{PT} symmetry and enables large electrically switchable NSC. Both MIC and NSC are highly tunable owing to field-induced Rashba and Zeeman splitting. Field induced bandgap reduction not only induces topological phase transition of bilayer AFM MnBi₂Te₄ from zeroplateau quantum anomalous Hall insulator into high Chern number quantum anomalous Hall insulator, but also leads to large nonlinear photocurrent response red-shifted down to a few

2

THz regime, suggesting $MnBi_2Te_4$ may serve as a promising platform for terahertz sensing and magneto-optoelectronic applications. The rich nonlinear photocurrent responses in time-reversal and inversion symmetry broken systems are inherently coupled with their crystal structure and magnetic symmetry, offering a promising route for probing and understanding the intrinsic electronic structure and potentially topological physics in magnetic quantum materials.

RESULTS

Microscopic theory of second-order nonlinear photocurrent

General second-order direct injection current (IC) and shift current (SC) under monochromatic electric field $E^b(t) = E^b(\omega_\beta)e^{-i\omega_\beta}$ with $\omega_\beta = \pm \omega$ in the clean limit are given by^{14,17,27}

$$\frac{dJ_{\rm IC}^a}{dt} = -\frac{\pi e^3}{\hbar^2} \int [d\mathbf{k}] \sum_{mn\sigma} f_{mn} \Delta^a_{mn} r^b_{nm} r^c_{mn} \delta(\omega_{nm} - \omega_{\beta}) E^b(\omega_{\beta}) E^c(-\omega_{\beta}),$$
(1)

$$J_{SC}^{a} = -\frac{i\pi e^{3}}{2\hbar^{2}} \int [d\mathbf{k}] \sum_{mn\sigma} f_{nm} \Big(r_{mn}^{b} r_{nm;k^{a}}^{c} - r_{nm}^{c} r_{mn;k^{a}}^{b} \Big) \delta(\omega_{nm} - \omega_{\beta}) E^{b}(\omega_{\beta}) E^{c}(-\omega_{\beta}),$$
(2)

where a, b, c are Cartesian indices, $r_{mn;k^a}^b = \frac{\partial r_{mn}^b}{\partial k^a} - ir_{mn}^b (\mathcal{A}_m^a - \mathcal{A}_n^a)$ is the gauge covariant derivative. $\mathbf{r}_{nm} = i\langle n | \partial_{\mathbf{k}} | m \rangle$ and $\mathcal{A}_n = i\langle n | \partial_{\mathbf{k}} | n \rangle$ are interband and intraband Berry connection, respectively. f_m is the Fermi-Dirac distribution with $f_{nm} \equiv f_n - f_m$, and $\hbar \Delta_{mn}^a \equiv v_{mm}^a - v_{nn}^a$ is the group velocity difference of band m and n. $[d\mathbf{k}] \equiv \frac{d\mathbf{k}}{(2\pi)^d}$ for d-dimension. Here e = -|e| carries a negative sign due to the negative charge of electron. We separate the product of the electric field amplitude into the symmetric real and antisymmetric imaginary parts,

$$E^{b}(\omega)E^{c}(-\omega) = E^{b}(\omega)E^{c^{*}}(\omega) = \operatorname{Re}(E^{b}E^{c^{*}}) + i\operatorname{Im}(E^{b}E^{c^{*}}), \quad (3)$$

$$E^{b}(-\omega)E^{c}(\omega) = E^{b^{*}}(\omega)E^{c}(\omega) = \operatorname{Re}(E^{b}E^{c^{*}}) - i\operatorname{Im}(E^{b}E^{c^{*}}).$$
(4)

For linearly polarized light, $E(\omega)$ is real, while for left/rightcircularly polarized light $E(\omega)$ is complex with $ImE^b(\omega)E^c(-\omega) =$ $-ImE^b(-\omega)E^c(\omega) \neq 0$. After symmetrization with $\pm \omega$, we have

$$\frac{d_{\mathbf{k}^{c}}^{\mu}}{dt} = -\frac{\pi e^{3}}{\hbar^{2}} \int [d\mathbf{k}] \sum_{mn\boldsymbol{\sigma}} f_{mn} \Delta_{mn}^{a} \{r_{nm}^{b}, r_{mn}^{c}\} \delta(\omega_{nm} - \omega) \operatorname{Re}\left(E^{b}E^{*}\right) -i\frac{\pi e^{3}}{\hbar^{2}} \int [d\mathbf{k}] \sum_{mn\boldsymbol{\sigma}} f_{mn} \Delta_{mn}^{a} [r_{nm}^{b}, r_{mn}^{c}] \delta(\omega_{nm} - \omega) \operatorname{Im}\left(E^{b}E^{c^{*}}\right),$$

where $\{r^b_{nm}, r^c_{mn}\} \equiv r^b_{nm}r^c_{mn} + r^c_{nm}r^b_{mn}$, and $[r^b_{nm}, r^c_{mn}] \equiv r^b_{nm}r^c_{mn} - r^c_{nm}r^b_{mn}$. We then arrive at

$$\frac{dJ_{\rm K}^a}{dt} = 2\eta_{\rm MIC}^{abc} {\rm Re}\left(E^b E^{c^*}\right) + 2i\eta_{\rm NIC}^{abc} {\rm Im}\left(E^b E^{c^*}\right),\tag{6}$$

where

$$\eta_{\rm NIC}^{abc} = -\frac{\pi e^3}{2\hbar^2} \int [d\mathbf{k}] \sum_{mn\sigma} f_{mn} \Delta_{mn}^a [r_{nm}^b, r_{mn}^c] \delta(\omega_{nm} - \omega), \tag{7}$$

$$\eta_{\rm MIC}^{abc} = -\frac{\pi e^3}{2\hbar^2} \int [d\mathbf{k}] \sum_{mn\sigma} f_{mn} \Delta_{mn}^a \{r_{nm}^b, r_{mn}^c\} \delta(\omega_{nm} - \omega), \tag{8}$$

 $\eta_{\rm NIC}^{abc}$ is the well-known NIC susceptibility, which vanishes under linearly polarized light. $\eta_{\rm MIC}^{abc}$ is an additional term, MIC susceptibility, arising from our microscopic derivation, which recovers the same formula as Yan's work²⁸. It's clear that $\eta_{\rm MIC}^{abc} = 0$ under timereversal symmetry. Detailed derivation of nonlinear photocurrent responses using density matrix formalism can be found in Supplementary Note 1. Similarly, we can separate SC into the well-known NSC and an additional term—MSC:

$$J_{SC}^{a} = J_{NSC}^{a} + J_{MSC}^{a} = 2\sigma_{NSC}^{abc} \operatorname{Re}(E^{b}E^{c^{*}}) + 2i\sigma_{MSC}^{abc} \operatorname{Im}(E^{b}E^{c^{*}}) , \qquad (9)$$
 where

$$\sigma_{\rm NSC}^{abc} = -\frac{i\pi e^3}{4\hbar^2} \int [d\mathbf{k}] \sum_{mn\sigma} f_{nm} \left(r_{mn}^b r_{nm;k^a}^c + r_{mn}^c r_{nm;k^a}^b \right) (\delta(\omega_{nm} - \omega) + \delta(\omega_{mn} - \omega))$$
(10)

$$\sigma_{\text{MSC}}^{abc} = -\frac{i\pi e^3}{4\hbar^2} \int [d\mathbf{k}] \sum_{mn\sigma} f_{nm} \left(r_{mn}^b r_{nm;k^a}^c - r_{mn}^c r_{nm;k^a}^b \right) (\delta(\omega_{nm} - \omega) - \delta(\omega_{mn} - \omega)).$$
(11)

Under time-reversal symmetry, the NSC and MSC susceptibilities can be rewritten in a compact form as follows,

$$\sigma_{\rm NSC}^{abc} = -\frac{\pi e^3}{4\hbar^2} \int [d\mathbf{k}] \sum_{mn\sigma} f_{nm} \left(R_{mn}^{a,b}(\mathbf{k}) + R_{mn}^{a,c}(\mathbf{k}) \right) \left\{ r_{nm}^b, r_{mn}^c \right\} \delta(\omega_{nm} - \omega),$$
(12)

$$\sigma_{\rm MSC}^{abc} = -\frac{\pi e^3}{4i\hbar^2} \int [d\mathbf{k}] \sum_{mn\sigma} f_{nm} \big(R_{mn}^{a,b}(\mathbf{k}) + R_{mn}^{a,c}(\mathbf{k}) \big) \Omega_{mn}^d(\mathbf{k}) \delta(\omega_{nm} - \omega),$$
(13)

where $R_{mn}^{a,b}(\mathbf{k}) = -\frac{\partial \phi_{mn}^{b}(\mathbf{k})}{\partial k^{a}} + \mathcal{A}_{m}^{a}(\mathbf{k}) - \mathcal{A}_{n}^{a}(\mathbf{k})$ is shift vector and $\phi_{nm}^{b}(\mathbf{k})$ is the phase factor of the interband Berry connection $r_{nm}^{b}(\mathbf{k}) = |r_{nm}^{b}(\mathbf{k})|e^{i\phi_{nm}^{b}(\mathbf{k})}$ and $\Omega_{mn}^{d} = i\epsilon_{dbc}r_{mn}^{b}r_{nm}^{c} = i(r_{mn}^{b}r_{nm}^{c} - r_{mn}^{c}r_{nm}^{b})$ is the local Berry curvature between band *m* and *n*. As indicated by Levi-Civita tensor ϵ_{dbc} , the direction of light propagation for MSC is along d, i.e., along $(E^b \times E^c)$, The MSC is vanishing in time-reversal invariant system since Berry curvature Ω_{mn}^{a} is an odd function and shift vector is even function with **k** under time-reversal symmetry. MSC can be induced by circularly polarized light in gyrotropic magnetic materials. During the preparation of this manuscript, we noticed that another paper²⁹ by de Juan derived an equivalent equation using the similar density matrix approach and Fei et al.³⁰ also proposed giant linearly polarized photogalvanic effect using a diagrammatic approach which is equivalent to MIC. In the present study, bilayer MnBi₂Te₄ is non-gyrotropic, hence it has vanishing MSC. Nevertheless, MSC in gyrotropic magnetic materials is worth for a further exploration which is closely related to magnetic bulk phototactic³¹. It should be noted that the term of "magnetic" nonlinear current defined in the MSC and MIC in Eqs. (8) and (11) is different from conventional spin current. Instead, it refers to the charge current which is present in magnetic materials but vanishes in intrinsic nonmagnetic materials. Furthermore, we can extend the above nonlinear SC and IC to nonlinear shift spin current and nonlinear injection spin current by substituting the current operator $j_{s_b}^a = -ev_a \rightarrow \frac{1}{2} \{s_b, v_a\}$, where $s_b = \frac{\hbar}{2} \sigma_b$ is spin operator with Pauli matrices σ_b . The extended nonlinear photospin current responses provide an essential route for exploring spin physics in condensed matter, which is currently under exploration and out of the scope in the present work.

Crystal structure and group theory of bilayer MnBi₂Te₄

Here we present a magnetic group theoretical analysis of bilayer AFM-*z* MnBi₂Te₄ (Fig. 1a, c) with interlayer AFM ordering of the Mn atoms aligned along the *z* direction, while group theoretical analysis of bilayer MnBi₂Te₄ with different magnetic orderings can be found in Supplementary Note 2. In general, the dichromatic group \mathcal{M} can be constructed by $\mathcal{M} = \mathcal{G}(\mathcal{H}) = \mathcal{H} \oplus (\mathcal{G} - \mathcal{H})\mathcal{T}$, where \mathcal{G} is the ordinary geometric point group, \mathcal{H} is the subgroup of \mathcal{G} of index 2, and \mathcal{T} is time-reversal operator. As a result, magnetic point group of bilayer AFM-*z* MnBi₂Te₄ is $\overline{3'm'} = D_{3d}(D_3) = \{E, 2C_3, 3C'_2, i\mathcal{T}, 2S_6\mathcal{T}, 3\sigma_d\mathcal{T}\}$. The character table of point group D_{3d} is included in Supplementary Table S1.

Two magnetic symmetry elements are illustrated in the plot, including twofold rotation symmetry around x-axis $C_{2x} = \mathcal{M}_y \mathcal{M}_z$, and the combination of mirror symmetry and time-reversal symmetry $\mathcal{M}_x T$. **d** Electronic band structure of bilayer AFM-z MnBi₂Te₄ near the Fermi level. **e** Contour plot of the energy difference between bottom conduction band and top valence band.

Without considering the ordering of spin, bilayer MnBi₂Te₄ is centrosymmetric with vanishing second-order nonlinear current responses. Taking into account the AFM-z structure, \mathcal{PT} symmetry is preserved in bilayer MnBi₂Te₄ with individual \mathcal{P} and \mathcal{T} symmetry being broken. In addition, as shown in Fig. 1b, bilayer AFM-z MnBi₂Te₄ holds a twofold rotation symmetry along *x*-axis $C_{2x} = \mathcal{M}_y \mathcal{M}_z$, and a combination of mirror symmetry and time-reversal symmetry $\mathcal{M}_x \mathcal{T}$.

For systems holding magnetic point group $\overline{3}'m'$ (such as bilaver and bulk AFM-z MnBi₂Te₄), both normal magnetoelectric coupling and topological axion coupling are symmetry allowed. The polar i-vectors (i.e., time-reversal symmetric and space-inversion antisymmetric vector), e.g., electric field *E* or electric polarization *P*, are represented by $A_{2u}(z)$ and $E_u(x, y)$ in D_{3d} group and they are timereversal symmetric but space-inversion antisymmetric. $A_{2q}(R_z)$ and $E_a(R_x, R_y)$ represent axial *i*-vectors, which are symmetric under both time reversal and space inversion. The general transformation of polar/axial *i*-/*c*-tensors under space inversion \mathcal{P}_{i} timereversal operation \mathcal{T} , and \mathcal{PT} can be found in Supplementary Table S2. We can see the two types of vectors are incompatible in D_{3d} group, e.g., $A_{2u} \otimes A_{2q} = A_{1u}$ does not contain total symmetric A_{1q} . The magnetic field **B** or orbital magnetization **M** are axial c-vectors, which are time-reversal antisymmetric but spaceinversion symmetric.

For magnetic point groups, we use Birss's notation³², where Γ_s is the total symmetric representation, Γ_m is the one-dimensional representation that corresponds to \mathcal{M} in which all elements of \mathcal{H} are represented by +1, and Γ_p is the pseudovector representation in group \mathcal{G} . We shall write the direct product representation $\Gamma_{m\otimes p} =$ $\Gamma_m \otimes \Gamma_p$ for axial *c*-vector. For magnetic point group $D_{3d}(D_3)$, we have $\Gamma_s = A_{1g}, \Gamma_m = A_{1u}, \Gamma_p = A_{2g} + E_g$. Thus, $\Gamma_{m\otimes p} = A_{2u} + E_u$. Consequently, $\Gamma_M \otimes \Gamma_E = \Gamma_P \otimes \Gamma_B = 2A_{1g} + A_{2g} + 3E_g$. Hence, the linear magnetoelectric coupling of 3m' structures has two independent nonvanishing components and corresponding orbital magnetoelectric polarizability. Now let's see how *c*-type secondorder current response under linearly polarized light such as MIC is enabled in $D_{3d}(D_3)$ by considering the following direct product $\Gamma_m \otimes \Gamma_j \otimes (\Gamma_{\mathbf{E}} \otimes \Gamma_{\mathbf{E}})^s = A_{1g} + 3A_{2g} + 4E_g$, indicating only one independent and nonvanishing susceptibility is allowed. For *i*-type second-order current response under linearly polarized light such as NSC, we have the direct product: $\Gamma_j \otimes (\Gamma_{\mathbf{E}} \otimes \Gamma_{\mathbf{E}})^s = (A_{2u} + E_u) \otimes (2A_{1g} + E_g) = A_{1u} + 3A_{2u} + 4E_u$. Hence, NSC is not symmetry allowed. In fact, NSC is immune to the time-reversal symmetry and can be determined by nonmagnetic point group. As bilayer/bulk MnBi₂Te₄ holds nonmagnetic point group D_{3d} with inversion symmetry, both NSC and NIC vanish. Similarly, *c*-type second-order current response under circularly polarized light such as MSC is forbidden in $D_{3d}(D_3)$ by considering the following direct product: $\Gamma_m \otimes \Gamma_j \otimes \Gamma_{\mathbf{E} \times \mathbf{E}^*} = 2A_{1u} + A_{2u} + 3E_u$ which does not contain total symmetric representation. The above analysis can be extended to other higher order optical/photocurrent responses in magnetic materials.

Nonlinear photocurrent in bilayer MnBi₂Te₄

Ground-state crystal structures of MnBi₂Te₄ were calculated using first-principles density functional theory^{33,34} implemented in the Vienna Ab initio Simulation Package (VASP)^{35,36} with the projector-augmented wave method³⁷. We then performed first-principles calculations of nonlinear photocurrent including MIC and NSC. Specifically, with the fully relaxed ground-state crystal structure, we constructed quasiatomic spinor Wannier functions and tight-binding Hamiltonian from Kohn–Sham wavefunctions and eigenvalues under the maximal similarity measure with respect to pseudoatomic orbitals^{38,39}. Using the developed tight-binding Hamiltonian, we then computed MIC and NSC susceptibility tensor using a modified WANNIER90 code⁴⁰ with a k-point grid of 1000 × 1000 × 1. Spin–orbit coupling was taken into account. More details can be found in the "Methods" section.

Figures 2a and b present the electronic structure and MIC susceptibility η_{MC}^{XX} in bilayer MnBi₂Te₄ with magnetic ordering in AFM-z ($\uparrow\downarrow$) and time-reversed AFM-z (tAFM-z, $\downarrow\uparrow$), respectively. The corresponding magnetic ordering is shown in Fig. 2a inset.

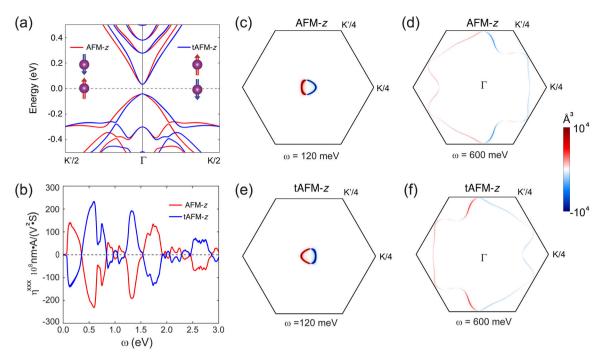

Fig. 2 Magnetic injection current (MIC) in bilayer MnBi2Te4 with magnetic ordering in AFM-z ($\uparrow\downarrow$) and time-reversed AFM-z (tAFM, $\downarrow\uparrow$). **a** Band structure of bilayer AFM-z and tAFM-z MnBi₂Te₄ with spin–orbit coupling taken into account. **b** Frequency-dependent magnetic injection current response of bilayer AFM-z and tAFM-z MnBi₂Te₄. **c**-**f** Microscopic distribution of MIC $f_{mn}\Delta_{mn}^a \{r_{nm}^b, r_{mn}^c\}\delta(\omega_{nm} - \omega)$ between top valence band and bottom conduction band at different frequencies of 120 and 600 meV in bilayer AFM-z and tAFM-z MnBi₂Te₄. It shows that MIC can be switched between two time-reversed magnetic orders AFM-z ($\uparrow\downarrow$) and tAFM ($\downarrow\uparrow$).

The **k**-space distribution of $f_{mn}\Delta^a_{mn}\{r^b_{nm}, r^c_{mn}\}\delta(\omega_{nm} - \omega)$ with a unit of Å³ at $\omega = 120$ meV and $\omega = 600$ meV are shown in Fig. 2c, d for bilayer AFM-z and in Fig. 2e, f for tAFM-z MnBi₂Te₄, respectively. This term arises from the large difference of the asymmetric group velocity Δ^a_{mn} and the absorption strength $\{r^b_{nm}, r^c_{mn}\}$ at time-reversed $\pm \mathbf{k}$ points, which eventually contributes to the large MIC in bilayer AFM-z and tAFM-z MnBi₂Te₄. The peak MIC conductivity is $\sim 2 \times 10^{10}$ nm · A · V⁻² · s⁻¹, two times the peak NIC in ferroelectric monolayer GeS¹⁷. More importantly, it demonstrates that the MIC can be switched upon magnetic ordering transition between AFM-z ($\uparrow\downarrow$) and its timereversed tAFM-z (tAFM, $\downarrow\uparrow$) configurations. With additional threefold rotation symmetry, we have $\eta_{MIC}^{xxx} = -\eta_{MIC}^{xyy} =$ $-\eta_{MIC}^{yxy} = -\eta_{MIC}^{yyx}$. Moreover, the presence of $\mathcal{M}_{y}\mathcal{M}_{z}$ symmetry leads to vanishing η_{MIC}^{yyy} . The switching of MIC for bilayer AFM-z and tAFM-z MBT can be understood from a symmetry analysis. The MIC is determined by the integral of $f_{mn}\Delta^a_{mn}\{r^b_{nm},r^c_{mn}\}\delta(\omega_{nm}-\omega)$ in the Brillouin zone. Under time-reversal operation, we have

$$\mathcal{T}\sum_{mn\mathbf{k}} f_{mn}(\mathbf{k}) \Delta_{mn}^{a}(\mathbf{k}) \{ r_{nm}^{b}(\mathbf{k}), r_{mn}^{c}(\mathbf{k}) \} \delta(\omega_{nm}(\mathbf{k}) - \omega)$$

$$= -\sum_{mn-\mathbf{k}} f_{mn}(-\mathbf{k}) \Delta_{mn}^{a}(-\mathbf{k}) \{ r_{nm}^{b}(-\mathbf{k}), r_{mn}^{c}(-\mathbf{k}) \} \delta(\omega_{nm}(-\mathbf{k}) - \omega)$$

$$= -\sum_{mn\mathbf{k}} f_{mn}(\mathbf{k}) \Delta_{mn}^{a}(\mathbf{k}) \{ r_{nm}^{b}(\mathbf{k}), r_{mn}^{c}(\mathbf{k}) \} \delta(\omega_{nm}(\mathbf{k}) - \omega).$$
(14)

Hence, MIC switches the sign in the AFM-z and tAFM-z MBT.

Van der Waals layered $MnBi_2Te_4$ hosts rich topology with varying magnetic orders that are different from the above AFM-z structure (Supplementary Table S3), subsequently the corresponding nonlinear current responses can be very different. For example, FM-x and FM-z magnetic ordering under external magnetic field (i.e., ferromagnetic ordering with magnetization aligned along x/z direction) holds inversion symmetry, hence has vanishing even-order nonlinear optical and photocurrent responses including SHG, NSC, NIC, MSC, and MIC. Supplementary Fig. S1 shows the band structure for the FM-z magnetic ordering where each band is symmetric with respect to $\pm \mathbf{k}$ points with vanishing MIC. In addition, for bilayer MnBi₂Te₄ with AFM-x magnetic ordering, the corresponding magnetic point group becomes $2'/m = C_{2h}(C_s) = C_s \oplus (C_{2h} - C_s)\mathcal{T} = \{E, \sigma_x, C_{2x}\mathcal{T}, i\mathcal{T}\}$, different from $\overline{\mathbf{3}}'m'$ for bilayer MnBi₂Te₄ with AFM-z magnetic structure. Nonetheless, bilayer AFM-x MnBi₂Te₄ preserves \mathcal{PT} -symmetry and allows for nonvanishing MIC response η_{MIC}^{XX} and η_{MIC}^{YXY} as shown in Supplementary Fig. S2. It is worth to point out that van der Waals layered MnBi₂Te₄ hosts rich topology with varying magnetic ordering. Probing MIC response can, therefore, help directly determine the intrinsic magnetic structure and hence potential topology of magnetic topological quantum materials owing to the intimate coupling between magnetic symmetry and nonlinear photocurrent responses.

NSC in electrically gated bilayer MnBi₂Te₄

Although both bilayer AFM-z and tAFM-z MnBi₂Te₄ hold the large MIC response as shown above, their Berry curvature $\Omega_n(\mathbf{k})$ and shift vector $R^a_{mn}(\mathbf{k})$ are vanishing due to $\mathcal{PT}\Omega_n(\mathbf{k}) = -\Omega_n(\mathbf{k}) = \Omega_n(\mathbf{k})$ and $\mathcal{PTR}^{a}_{mn}(\mathbf{k}) = -R^{a}_{mn}(\mathbf{k}) = R^{a}_{mn}(\mathbf{k})$. Hence, no NSC and Berry curvature related physics would be expected in \mathcal{PT} -symmetric system. In fact, one can take the wave functions to be real (due to the \mathcal{PT} transformation). Then the phase effect is absent and the shift vector and Berry curvature become zero in \mathcal{PT} -symmetric system. However, one can apply Berry curvature engineering via electric gating to break the \mathcal{PT} symmetry in the pristine bilayer $MnBi_2Te_4^{41}$. Here we apply an external electric field along the out of plane direction to bilayer MnBi2Te4. Figure 3a, b show the calculated electronic structure and NSC in bilayer MnBi₂Te₄ under an external electric field $E_z = 10 \,\text{mV}$ Å⁻¹ with magnetic ordering AFM-z (1). Large Rashba and Zeeman spin splitting are indicated in Fig. 3a, which we will discuss soon. The peak NSC conductivity is ~ 1000 nm $\cdot \mu$ A \cdot V⁻², which is 50 times larger than that in GeS¹⁷. In addition, Fig. 3c-f presents the microscopic distribution of NSC,

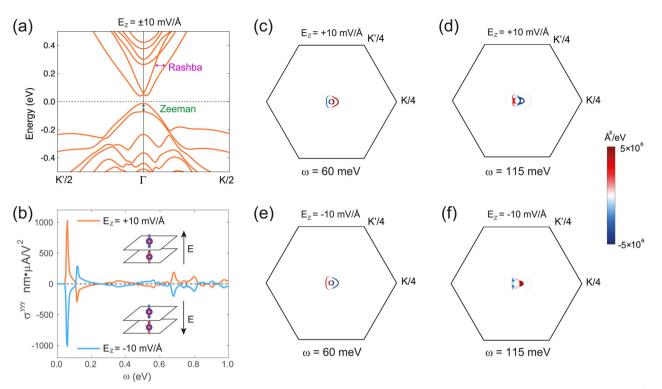

Fig. 3 Normal shift current (NSC) in bilayer MnBi2Te4 with magnetic ordering AFM-z ($\uparrow\downarrow$) under external electric field $E_z = 10 \text{ mV} \text{ Å}^{-1}$. a Band structure of bilayer AFM-z under external electric field $E_z = 10 \text{ mV} \text{ Å}^{-1}$. b Frequency-dependent NSC response of bilayer AFM-z MnBi₂Te₄ under external electric field $E_z = \pm 10 \text{ mV} \text{ Å}^{-1}$. c-f Microscopic distribution of NSC $\sum_{mn\sigma} f_{nm}(r_{mn}^b r_{n:k^a}^c + r_{mn}^c r_{n:k^a}^b)(\delta(\omega_{nm} - \omega) + \delta(\omega_{mn} - \omega))$ at different frequencies in bilayer AFM-z external electric field $E_z = \pm 10 \text{ mV} \text{ Å}^{-1}$. It demonstrates that NSC can be switched by applying electric field along +z/-z out-of-plane directions.

 $\sum_{mno} f_{nm}(r_{mn}^{b}r_{nm;k^{o}}^{c} + r_{mn}^{c}r_{nm;k^{o}}^{b}) (\delta(\omega_{nm} - \omega) + \delta(\omega_{mn} - \omega)), \text{ with a unit of Å}^{3} (eV)^{-1} \text{ at two frequencies } (\omega = 60 \text{ meV and } \omega = 115 \text{ meV}) \text{ in bilayer AFM-z with } E_{z} = \pm 10 \text{ mV Å}^{-1}. \text{ From the symmetry transformation } \mathcal{M}_{y}\mathcal{M}_{z}E_{z} = -E_{z}, \text{ we can see that the direction of NSC along y under linearly y-polarized light can be flipped by switching the electric field from <math>+z$ to -z. The electric field of 10 mV Å^{-1} can be achieved in few-layer 2D materials when the thickness is on the order of ~nm. Recently, Xiao et al. measured nonlinear anomalous Hall effect in trilayer and four-layer WTe₂ using an electric field up to ~40 mV Å^{-126}. Similar to MIC, NSC, and NIC, nonlinear anomalous Hall effect is also originated from a type of second-order nonlinear current responses due to the intraband Berry curvature dipole. We therefore expect that it may be possible to carry out experimental measurement of NSC using an electric field of ~10 mV Å^{-1}.

Similar to the case of MIC, $\sigma_{\rm NSC}^{yyy} = -\sigma_{\rm NSC}^{yxx} = -\sigma_{\rm NSC}^{xyx} = -\sigma_{\rm NSC}^{xxy}$ under threefold rotation symmetry, and $\sigma_{\rm NSC}^{xxx}$ vanishes due to $\mathcal{M}_{x}\mathcal{T}$ symmetry. It is important to realize that upon linearly polarized incident light along x direction, the response of NSC in the electrically gated bilayer AFM-z and tAFM-z MnBi₂Te₄ is governed by σ_{NSC}^{yxx} with nonlinear photocurrent generated along y only. In contrast, under the same linearly x-polarized light, the response of MIC is dominated by $\eta_{
m MIC}^{
m xxx}$ with nonlinear photocurrent generated along x only. Moreover, NSC does not switch in bilayer AFM-z ($\uparrow\downarrow$) and time-reversed AFM-z (tAFM, $\downarrow\uparrow$) MnBi₂Te₄, indicating that NSC cannot be reversed under \mathcal{T} corresponding to its dissipative and non-reciprocal nature⁴². In addition, as aforementioned, NSC vanishes when electric field is absent, while MIC always exists regardless of electric field. As shown in Figs. 2 and 3, both NSC and MIC in bilayer AFM-z MnBi₂Te₄ have strong responses at low-energy regime (e.g., two strong NSC peaks at 60 and 115 meV under $E_z = 10 \text{ mV } \text{\AA}^{-1}$ and two strong MIC peaks at 120 and 600 meV), making them particularly attractive for terahertz and infrared sensing.

Tunable nonlinear photocurrent in bilayer MnBi₂Te₄

Both NSC and MIC are highly tunable under varying electric field. Figure 4a shows the electric field-dependent band structure. The bandgap decreases upon increasing vertical electric field until a critical field of $E_z = 25 \text{ mV } \text{\AA}^{-1}$, where it undergoes topological phase transition from zero-plateau quantum anomalous Hall insulator with Chern number $C_n = 0$ to high Chern number quantum anomalous Hall insulator ($C_n = 3$). The nontrivial topology is evinced in the Berry curvature shown in Fig. 4b, which is localized around the center of the Brillouin zone. The integration of Berry curvature yields a high Chern number of $C_n = 3$. As aforementioned, electric field can introduce large Rashba and Zeeman splitting in bilayer AFM-z MnBi₂Te₄. In Fig. 4c, d we show the corresponding spin polarization at the energy of 0.6 eV with AFM-z and tAFM-z magnetic ordering under a vertical electric field of $E_7 = 10 \text{ mV }\text{\AA}^$ which confirms large spin splitting with threefold rotation symmetry under finite electric field. Under the same electric field, spin polarization in AFM-z and tAFM-z are related by time-reversal ${\cal T}$ operation. However, for the same magnetic configuration AFM-z or tAFM-z, the spin polarization under electric field along +z and -zare related by \mathcal{PT} operation (see Supplementary Fig. S3). Electric field-induced large spin splitting and distinct spin polarization suggest that bilayer AFM-z MnBi₂Te₄ could serve as a rich platform for developing electrically controlled spintronics.

Electric field-induced Rashba and Zeeman splitting reduces the electronic gap, thereby shifting the nonlinear photocurrent responses such as MIC and NSC to the THz regime. Figure 4e, f shows field-dependent NSC and MIC responses in bilayer AFM-z MnBi₂Te₄ under varying electric field. It clearly demonstrates that

the strength of NSC response increases under increasing electric field until $E_z = 23 \text{ mV Å}^{-1}$, and the MIC conductibility remains very large until $E_z = 23 \text{ mV Å}^{-1}$. More importantly, the low-energy peak of NSC and MIC response linearly decreases to ~25 meV upon increasing field up to $E_z = 23 \text{ mV Å}^{-1}$. It's worth to point out that NSC will switch the sign upon the switching of electric field from +z to -z, however, the sign of MIC will remain the same. This is another way to distinguish NSC and MIC. We would like to mention that the NSC and MIC calculated here is solely contributed by bulk response. Topologically protected edge states in QAHI will also contribute nonlinear current responses, which is outside the scope of this work and needs to be explored in future.

DISCUSSION

The distinct directional dependence and switching behavior of NSC and MIC under different electric field and magnetic ordering provide a fundamental basis to distinguish these two current responses in experiment. First, as shown above, under linearly polarized light, MIC can be generated in \mathcal{PT} -symmetric system such as bilayer AFM-z MnBi₂Te₄. NSC, though absent in the \mathcal{PT} -symmetric system, can be enabled via electric gating. Moreover, for electrically gated bilayer AFM-z and tAFM-z MnBi₂Te₄ under linearly x-polarized light, NSC susceptibility tensor element $\sigma_{\rm NSC}^{\rm yxx}$ contributes a large nonlinear photocurrent along y only, while MIC susceptibility tensor element $\eta_{\text{MIC}}^{\text{XXX}}$ contributes a large nonlinear photocurrent along x only. More importantly, nonlinear photocurrent from NSC can be switched by applying vertical electric field along +z/-z direction, while nonlinear photocurrent from MIC can be reversed by inducing magnetic transition between AFM-z and tAFM-z. Furthermore, different magnetic orderings (e.g., AFM-z, AFM-x, FM-z, and FM-x) yield distinct magnetic point group, leading to different directional dependence of nonlinear photocurrent. Such rich coupling between the magnetic ordering and nonlinear photocurrent responses presents itself a powerful tool for investigating magnetic symmetries, structures, and interactions in magnetically ordered crystals as well as imaging magnetic domain walls.

Bilayer AFM-z MnBi₂Te₄ possesses large MIC and NSC that are highly tunable under electric field with the first low-energy peak red-shifted down to 25 meV (i.e., ~6 THz), offering a promising platform for THz sensing of extreme nonlinear quantum phenomena. The large MIC response is originated from the large absorption strength and asymmetry of the group velocity difference at time-reversed ±k points due to the breaking of time-reversal symmetry. The large NSC response comes from the strong absorption strength and the large shift vector which is related to large inter-band Berry curvature. Topological insulators including the MBT studied here usually have small bandgap, large inter-band transition matrix elements, and large Berry curvature, which is expected for most magnetic topological insulators with symmetry-allowed nonlinear photocurrent. \mathcal{PT} symmetry plays an important role in the present case, and it is also crucial for non-Hermitian magnetic structures with balanced gain and loss⁴³. In addition to MIC and NSC, MSC presents another interesting second-order photocurrent response, which vanishes in timereversal invariant systems. MSC can be induced by circularly polarized light in gyrotropic magnetic materials. Furthermore, nonlinear SC and IC can be extended to nonlinear shift spin current and nonlinear injection spin current, yielding nonlinear photo-spin current response. This will provide an essential route for exploring spin physics in condensed matter, which is currently under exploration and out of the scope of the present work.

In summary, the intimate coupling between intrinsic magnetic point group and nonlinear optical/photocurrent responses makes nonlinear spectroscopy and imaging a powerful tool for investigating magnetic symmetries, structures, and interactions in magnetically ordered crystals. In particular, we predicted that \mathcal{PT} -symmetric magnetic topological quantum material bilayer MnBi₂Te₄ possesses large, magnetically switchable MIC in the THz regime. Although NSC vanishes in \mathcal{PT} symmetric system, electric field breaks the \mathcal{PT} -symmetry in bilayer AFM-z MnBi₂Te₄, and enables large NSC response at the IR regime. More importantly,

NSC can be switched by vertical electric field and MIC be switched upon magnetic transition, however, NSC (MIC) will not be switched by magnetic transition (electric field). Due to the magnetic group symmetry of bilayer AFM-z MnBi₂Te₄, MIC, and NSC yield photocurrent that are perpendicular to each other upon linearly x/y-polarized light, hence can be distinguished. Very excitingly, electric gating can efficiently tune the large nonlinear photocurrent response down to 6 THz, suggesting bilayer AFM-z MnBi₂Te₄ as an exciting platform for THz and magnetooptoelectronic applications as well as 2D spintronics that are electrically and magnetically tunable. The present work reveals that nonlinear photocurrent responses governed by NSC, NIC, MSC, and MIC provide a powerful spectroscopic/imaging tool for the investigation of magnetic structures and interactions, which could be particularly fruitful for probing and understanding magnetic topological quantum materials.

METHODS

Ground-state crystal and electronic structure

Ground-state crystal structures of MnBi₂Te₄ were calculated using the firstprinciples density functional theory^{33,34} implemented in the VASP^{35,36} with the projector-augmented wave method³⁷ and a plane-wave basis with an energy cutoff of 400 eV. We employed the generalized-gradient approximation of exchange-correlation energy functional in the Perdew–Burke–Ernzerhof⁴⁴ form. A Hubbard U correction with U = 4 eVwas applied to Mn atoms to reduce the self-interaction error present in DFT-PBE. We further adopted a Monkhorst–Pack k-point sampling of 11 × 11 × 1 for the Brillouin zone integration and DFT-D3 functional⁴⁵ to account for weak interlayer dispersion interactions. The convergence criteria for maximal residual force was set to 0.005 eV Å⁻¹, and the convergence criteria for electronic relaxation was set to 10⁻⁶ eV.

First-principles calculations of nonlinear photocurrent

With the fully relaxed ground-state crystal structure, we constructed quasiatomic spinor Wannier functions and tight-binding Hamiltonian from Kohn-Sham wavefunctions and eigenvalues under the maximal similarity measure with respect to pseudoatomic orbitals^{38,39}. Spin-orbit coupling was taken into account. Total 120 quasiatomic spinor Wannier functions were obtained from the projections onto $Mn's \ s$ and d pseudoatomic orbitals, Te's s and p pseudoatomic orbitals, and Bi's s and p pseudoatomic orbitals for bilayer MnBi₂Te₄. Using the developed tight-binding Hamiltonian, we then computed MIC and NSC susceptibility tensor using a modified WANNIER90 code⁴⁰. A small imaginary smearing factor η of 5 meV was applied to fundamental frequency. A k-point grid of $1000 \times$ 1000×1 was adopted, which is dense enough to reach the convergence as shown in Supplementary Fig. S4. Tight-binding Hamiltonian was not directly symmetrized, however, we carefully inspect the resulted electronic structure by comparing the calculated band structures with the recent publications by Li et al.⁴ and Du et al.⁴¹ and our calculations are in good agreement with their results. Second, the electronic band structure of bilayer AFM-z MBT (Fig. 1d) and the contour plot of the energy difference between bottom conduction band and top valence (Fig. 1e) demonstrate the presence of \mathcal{PT} and C_3 symmetries.
