BRIEF COMMUNICATION OPEN

Drinking water bacterial communities exhibit specific and selective necrotrophic growth

Ioanna Chatzigiannidou¹, Ruben Props¹ and Nico Boon¹

Physicochemical water disinfection methods result in the reduction of bacterial concentrations by orders of magnitude, but not in the total elimination of the bacterial community. As such, the dead bacterial biomass may act as a carbon and nutrient source for the survivor populations. The ability of bacterial strains to grow on dead bacterial cells has been described before as necrotrophy. We investigated the impact of killed bacterial biomass of two different bacterial strains on the growth potential of natural drinking water microbial communities. Many indigenous bacterial taxa could grow on dead biomass, with the total bacterial concentration increasing from 10^4 to 10^8 cells/ml. Necrotrophic growth was specific (43 enriched taxa) and selective (i.e. enriched taxa were dependent on the type of dead biomass). The potential of natural water communities to grow necrotrophically has remained underexplored. Nevertheless the phenomenon can have a big impact in water quality and deserves more attention.

npj Clean Water (2018) 1:22; doi:10.1038/s41545-018-0023-9

INTRODUCTION

Water disinfection is an essential procedure to decrease the microbial load in water sources and make them safe for consumption. Disinfection can be attained chemically (e.g. chlorination) or physically (e.g. heat, UV). Although the procedure is able to decrease the microbial load, it cannot eliminate all microorganisms. At the same time, the dead bacterial cells remain in the water resulting in an increase of available nutrients (e.g. nitrogen, carbon and phosphorus), which are important elements for bacterial growth. Current research on disinfection does not take into account the impact of this biomass excess on the survivor populations and the water quality. However, certain bacterial strains can use dead bacterial cells as a nutrient source,^{1,2} a phenomenon referred to as necrotrophy or necrotrophic growth.¹ Necrotrophic growth has been studied in axenic cultures, but it has not been described before in a mixed microbial community.

In this study, we tested how the natural microbial community of a drinking water source responds to an excess dead bacterial biomass (10^7 cells/ml). Evian bottled water was used as a benchmark water source due to its stable microbial community. *Escherichia coli* (Gram[−]) and *Lactobacillus brevis* (Gram⁺) were added to the water to test if the type of the dead biomass would drive the structure of the microbial community. Dead biomass was generated either by autoclavation (physical disinfection) or 5% chloroform (fumigation—chemical disinfection) to examine whether the killing method influences the response of the natural community. Yeast extract (YE) (0.5 g/l) supplementation was used as benchmark control. The concentration of the living and dead biomass was monitored with flow cytometry (FC) in 24 intervals over 7 days. 16S rRNA gene amplicon sequencing was used to determine the bacterial community composition.

RESULTS AND DISCUSSION

The microbial community as a whole could grow necrotrophically on the different types of dead biomass (Fig. 1a). The cell concentration increased from 10^4 cells/ml to 10^7 – 10^8 cells/ml. Samples that received dead biomass reached higher cell concentrations than the positive control, although the added carbon load was less (chemical oxygen demand was 8.5–22.8 mg/l for dead biomass samples and 675 mg/l for YE) (Fig. 1b). The *E. coli*-supplemented samples reached significantly (p -value <0.01) higher cell concentrations than the ones supplemented with *L. brevis* (Fig. 1a). The phenomenon that dead Gram⁺ cells exhibited lower capacity to stimulate growth was previously observed in axenic cultures,^{1,2} potentially due to their robust cell wall that increases the difficulty for other bacteria to access their nutrients.¹ An alternative explanation could be that an aquatic water community, consisting mostly of Gram[−] strains, has adapted more to the consumption of Gram[−] dead biomass.

16S rRNA gene amplicon sequencing revealed that there were compositional differences at the genus level between treated and non-treated samples. The most abundant phyla, identified in all samples, were *Proteobacteria*, followed by *Bacteroides*, *Actinobacteria*, and *Firmicutes*, as it has shown before for bottled water microbial communities.^{3,4} Nevertheless, there were differences at the genus level between treated and non-treated samples. The most abundant taxa identified in the control samples were unclassified *Burkholderiales* (Fig. 2). The YE-treated samples revealed the most similar bacterial composition among the biological replicates, with *Hydrogenophaga* being the most abundant genus (Fig. 2). The most abundant genera in the necrotrophic grown samples were *Brevudimonas*, *Stenotrophomonas*, *Pseudomonas* and *Rhizobium* (Fig. 2). However, large variability was observed in relative abundances between treatments as well as biological replicates of the same treatment (Fig. 2). The variability within biological replicates could not be

The displayed concentration represents the average of four biological replicates and the ribbon the standard deviation. **b** Final cell concentration of natural drinking water bacterial community after necrotrophic growth compared to the added COD concentration of the different treatments

Fig. 2 **a** Relative abundances of the 10 most abundant genera. **b** Absolute abundances of 10 most abundant genera. Dots depict the total cell density per sample

explained by differences in absolute abundances, in all cases (Fig. 2b). Thus necrotrophic growth may possibly be subject to stochasticity and the initial bacterial composition.

To examine the effect of necrotrophy on specific taxa, the differentially abundant taxa between the non-treated samples and each treatment were identified (Fig. 3a). Forty-three taxa were enriched in at least one of the treatments ($p_{adj} < 0.01$). Moreover, the specific effect of the supplemented biomass was investigated by identifying the differentially enriched taxa between the two strains that were used as supplements or the two methods of generating dead biomass. Twenty-three taxa were differentially enriched in *E. coli*- versus *L. brevis*-supplemented samples (Fig. 3b), whereas there were no significant ($p_{adj} > 0.01$) differences between autoclaved or fumigated supplements.

The changes on the bacterial community due to necrotrophy were also depicted in the alpha diversity of the samples. Alpha diversity is the within-sample diversity, with taxonomic to refer to the observed diversity based on the amplicon sequencing data, while phenotypic diversity refers to the changes of the phenotypic profile (fingerprint) of the community, measured by FC.⁵ Lower taxonomic and phenotypic alpha diversity were observed for all treated samples compared to the negative control (Fig. 3c, d). The

above indicates a selective effect with specific taxa/phenotypes benefiting more by the available dead biomass.

This study revealed that the natural bacterial community of drinking water exhibited necrotrophic growth. However, certain bacterial taxa exhibited better efficacy at necrotrophy, as indicated by the differential abundance of the enriched taxa and the lower diversity of the treated samples. Moreover, the differentially enriched taxa between *E. coli*- and *L. brevis*-treated samples revealed that the type of biomass affected the behaviour of the community.

Overall, the increased cell concentration and the altered community composition has the potential to greatly influence the water quality. For example, the decreased diversity observed during necrotrophy could lead to decreased invasion resistance.^{6,7} While the short amplicon sequences prevented the identification of pathogenic strains that were specifically benefiting from necrotrophy, isolation with selective medium, or targeted PCR/qPCR could be used in the future to identify possible pathogens.² Nevertheless, we argue that an excess of dead bacterial biomass can have a substantial impact on oligotrophic microbial dynamics and thus further research is needed to determine the impact of necrotrophic growth during water disinfection.

Fig. 3 **a** Differentially enriched taxa in treated samples compared to non-treated control samples. Differentially abundant taxa were calculated using the package DESeq2 in R (p -value < 0.01). **b** Differentially abundant taxa in *E. coli*-treated samples compared to *L. brevis*-treated samples. Negative values indicated that the taxa were more abundant in *E. coli*-treated samples. Phenotypic Diversity (D_2) **c** or taxonomic diversity (D_2) **d** calculated from flow cytometric fingerprinting or 16S rRNA amplicon sequencing data accordingly for the last time point ($t = 7$ days) using the Hill Number framework (order 2). Control (non-treated) samples exhibited the highest diversity in both cases

MATERIAL AND METHODS

Dead biomass production

Escherichia coli (DSM 2840) and *Lactobacillus brevis* (LMG 18022) were grown overnight in LB (Sigma Aldrich, Belgium) and MRS broth (Oxoid, UK), respectively. The cultures were resuspended in PBS (phosphate-buffered saline tablets; Sigma Aldrich, Belgium) and split in two. One part of the solution was autoclaved (following standard autoclavation cycle 121 °C for 15 min) and the other part was fumigated by addition of 5% chloroform (Honeywell Fluka, Sigma Aldrich, Belgium) for 1 h. The samples treated with chloroform were subsequently washed twice with PBS to remove the remaining chemical. Flow cytometry was used to calculate the cell concentration in each sample.

Fifty microliters of each condition were plated in LB (Sigma Aldrich, Belgium) and MRS agar plates (Oxoid, UK), respectively, and incubated in 28 °C for 48 h to verify that there were no survivals. There were no colonies observed in any of the agar plates.

The COD (chemical oxygen demand) was analysed with Nanocolor® kits (028; Macherey-Nagel).

Experiment

Evian bottled water (Evian, France) was used as the drinking water source. Equal concentrations (10^7 cells/ml, as calculated by flow cytometry) of autoclaved *E. coli*, fumigated *E. coli*, autoclaved *L. brevis* and fumigated *L. brevis* were added in different bottles of drinking water. This concentration of dead cells corresponded to a COD of 22 mg/l for autoclaved *E. coli*, 12 mg/l for fumigated *E. coli*, 22.5 mg/l for autoclaved *L. brevis* and 8.5 mg/l for fumigated *L. brevis*. Addition of 0.5 g/l (675 mg/l COD) yeast extract (Oxoid, UK) was used for the positive control. Every treatment was done in

quadruplicates and all the samples were maintained in 28 °C for a period of 7 days.

Flow cytometry

In 24 h interval, samples were taken from every bottle for flow cytometric measurements. The samples were diluted in sterile PBS and stained with the nucleic acid stain SYBR® Green I and Propidium iodide that stains permeabilized cells. SYBR Green I (10,000x concentrate in dimethyl sulfoxide (DMSO); Invitrogen) was diluted 100 times in 0.22- μ m-filtered DMSO (IC Millex, Merck, USA) and Propidium iodide (20 mM in DMSO; Invitrogen, USA) was diluted 50 times. Following, they were incubated in 37 °C for 13 min. Measurements were performed with a FACSVerse cytometer (BD Biosciences, Belgium). The performance of the instrument was monitored daily and the instrument was calibrated with the CS&T calibration beads (BD Biosciences, Belgium). The blue laser (488 nm) was used for the excitation of the stains. A minimum of 10,000 cells per sample were measured to allow accurate quantification.

The data of each sample were denoised from (in)organic noise by a filtering approach using the *flowCore* package (v1.38.1) in R (v3.3.2). The bacterial cell population was extracted by a gate applied on the primary fluorescence emission channels (green (530/30 nm) and red (>670 nm)).

DNA extraction and amplicon sequencing

The remaining water volume was filtered through 0.2 μ m filter and the filters were stored in -20 °C. DNA was extracted with the PowerWater Kit (MO BIO, Belgium). The quality of the DNA extracts was validated by means of agarose gel electrophoresis and via PCR. The quality of the PCR product was determined with agarose

gel electrophoresis to ensure that no inhibition of the PCR took place.

The DNA extracts were sent to LGC Genomics (GmbH, Berlin, Germany) for 16S rRNA amplicon sequencing. High-throughput amplicon sequencing of the V3–V4 hypervariable region⁸ (using the 341F CCTACGGGNGGCWGCAG and 785Rmod GACTACHVGGG-TATCTAAKCC primers) was performed with the Illumina MiSeq platform, according to the manufacturer's guidelines. Analysis of the amplicon data was performed with the software package MOTHUR (v.1.33.3).⁹ Contigs were generated by merging the forward and reverse reads and they were further aligned to the SILVA v123 database. Sequences that did not correspond to the V3–V4 region as well as sequences with ambiguous bases or more than 12 homopolymers were removed. The aligned sequences were filtered and dereplicated. UCHIME was used to remove chimeras¹⁰ and the sequences were clustered in OTUs with 97% similarity with the cluster.split command (average neighbour algorithm). OTUs were subsequently classified using the SILVA v123 database.

Data analysis

All statistical analysis was performed in R (v3.3.2). Welch two-sample *t*-test, 'stats' package, was used to test for significant difference between cell concentrations of samples fed with *E. coli* or *L. brevis*. The phenotypic fingerprint based on flow cytometry data was calculated using the *PhenoFlow* package (v1.0) in R (v3.3.2).⁵ The same package was used to calculate the phenotypic alpha diversity based on the Hill Number framework.

The OTU contingency table was imported in R. OTUs with no more than one read in every sample (singletons) were removed.¹¹ The pre-processed reads were normalized over the cell concentrations acquired with flow cytometry to receive the absolute OTU abundances.¹² The graphs representing the 10 most relative or absolute abundant genera were generated using the phyloseq package¹³ in R (v3.3.2). Finally the differentially enriched samples were calculated using the DESeq2 package (v1.16.1) after the data underwent prevalence filtering (prevalence > 0.05).¹¹ The adjusted *p*-value (*p*_{adj}) was calculated based on Benjamini and Hochberg method and *p*_{adj} < 0.01 was considered significant. The taxonomic alpha diversity was also calculated according to the Hill Number framework (order 2).

DATA AVAILABILITY

Flow cytometry data (.fcs format) are available on the FlowRepository archive under repository ID FR-FCM-ZYG7. Sequences are available on the NCBI Sequence Read Archive (SRA) under accession number SRP130062.
