

Proximate and ultimate causes of the bactericidal action of antibiotics

Fernando Baquero and Bruce R. Levin 

Abstract | During the past 85 years of antibiotic use, we have learned a great deal about how these ‘miracle’ drugs work. We know the molecular structures and interactions of these drugs and their targets and the effects on the structure, physiology and replication of bacteria. Collectively, we know a great deal about these proximate mechanisms of action for virtually all antibiotics in current use. What we do not know is the ultimate mechanism of action; that is, how these drugs irreversibly terminate the ‘individuality’ of bacterial cells by removing barriers to the external world (cell envelopes) or by destroying their genetic identity (DNA). Antibiotics have many different ‘mechanisms of action’ that converge to irreversible lethal effects. In this Perspective, we consider what our knowledge of the proximate mechanisms of action of antibiotics and the pharmacodynamics of their interaction with bacteria tell us about the ultimate mechanisms by which these antibiotics kill bacteria.

Antibiotics have been used to treat bacterial infections for nearly 85 years, or more than a century if Paul Ehrlich’s arsenate, also called ‘compound 606’ or ‘Salvarsan’, is included¹. During this time, we have learned a great deal about these drugs. We know their molecular structure and that of their targets in the bacteria, how they bind to those targets and the immediate consequences of that binding on the physiology and structure of the exposed bacteria. Curiously, for the vast majority of antibiotics, what is not known, and is subject of some controversy, is how these drugs actually kill bacteria² and/or prevent their replication³. For example, why do some ribosome-targeting drugs, such as most but not all aminoglycosides, rapidly kill bacteria, whereas others, such as the macrolides, prevent replication and kill at low rates if at all? Why is inhibition of protein synthesis lethal in some cases and only static in others? It is useful to put this question into the context of what Ernst Mayr described as cause and effect in evolutionary biology^{4–6}. Mayr used ‘proximate causation’ to refer to immediate factors (for example, physiology or mutation) of processes and ‘ultimate causation’ to refer to the ‘final reasons’ for the outcome (for example,

natural selection or evolution). We use these terms similarly to respectively refer to the primary biochemical mechanisms by which antibiotics exert their action (the traditional ‘mechanisms of action’) and the final result of the process (bactericidal action). We know a great deal about the proximate causes of antibiotic action, how antibiotics interact with the cell, but we know vastly less about the ultimate causes, why, when confronted with antibiotics, bacteria die, and why they do so at different rates.

In this Perspective, we consider what the knowledge of the proximate causes of antibiotic action tells us about these ultimate causes, and what we know and need to know to truly understand how antibiotics kill bacterial cells. We discuss these processes in general and for antibiotics of specific classes.

When is a bacterium dead?

Central to understanding how antibiotics kill or prevent the replication of their target bacteria is knowing when a bacterium is dead and when it is no longer capable of dividing. Whereas the former is irreversible, the latter is expected to be transient, but if cell division is prevented for a long time, the bacterium is effectively dead

by convention. In an essay written many years ago, Peter Medawar defined death as the non-reversible loss of individuality, a state that requires physical destruction of the biological “structure of the self” (REF.⁷), dissipation of the internal content of the cell by irreversible membrane damage or irreversible breaks and disorganization of its individual genetic content produces death. Other changes in the structural and physiological status quo may not result in death, but from the limited perspective of bench scientists conveniently working with bacteria whose viable cell densities can be estimated from data on colony-forming units, if a bacterium cannot form a colony, it is officially dead.

Deadly events are those for which the antimicrobial agents or procedures immediately destroy the integrity of the cell (similar to a crash or explosion), whereas deadly processes resemble a mortal illness (acute or chronic), finally leading to the collapse of physical or genetic individuality. Probably, most of the deadly processes result from the antimicrobial-induced starvation or destruction of a key cellular components needed to maintain the cellular envelope or genetic integrity. In this way, an antimicrobial, including chemical disinfectants, could produce virtually immediate death of a bacterium at higher concentrations and at lower concentrations could produce morbidity and a slow approach to death. Chlorine and its effects on the membranes of bacteria is an excellent example of this^{8,9}.

One antibiotic, many actions

Traditionally, *in vitro* studies of bacteria and antibiotics ignore the inconvenient reality of the physical and temporal heterogeneity of bacterial populations and their interactions with these drugs. However, it is clear that for a comprehensive understanding of how antibiotics do their bactericidal and bacteriostatic actions, this complexity must be considered, but rarely is. For convenience and the parametric reductionism manifest in so much of biology, the study of antibiotic action is treated as a static process⁷, and the use of minimum inhibitory concentrations as the unique pharmacodynamic parameter is reflection of this approach¹⁰. The interaction

between antibiotics and their target bacteria is a dynamic process. Bacteria are in a continuous state of flux: their populations are heterogeneous and composed of cells of a diversity of ages (corresponding to the time since they were produced by cell division) and physiological states. Antibiotics act at variable concentrations, and their effects on bacteria might differ with the number of molecules effectively interacting with each cell.

The concept of ‘hormesis’ applies here. The term ‘hormesis’ was coined by Southam and Ehrlich in 1943 to describe biphasic dose responses of the same compound acting on a biological substrate¹¹. This term was resurrected by Julian Davies in reference to different types of action at different antibiotic concentrations, ranging from promoting death to serving as signals in interbacterial communication^{12,13}. Hormesis is considered a fundamental concept in medicine and biology^{14,15}. Hormesis and, more generally, multiphasic processes are certainly a reality for the antibiotic treatment of bacterial infections. In treated patients, the concentrations of antibiotics vary in time and space (intracellular, tissues or organic fluids); pharmacokinetics is a highly dynamic process. The individual cells of the target bacteria are confronted with variable concentrations of the treating drug, which has different but overlapping effects on their physiology. Antibiotic susceptibility tests based on agar diffusion

or the response of bacteria to antibiotics in continuous culture¹⁶ offer a more realistic view of the antibiotic action than the gold standard of estimating the minimum concentration of antibiotics necessary to prevent replication (the minimum inhibitory concentration) by exposing well-mixed bacterial populations at relatively low densities growing exponentially to fixed antibiotic concentrations.

We have considered hormesis for individual cells, as it should be. However, the consequences of the ‘one antibiotic, many actions’ paradigm are particularly relevant in assays to determine killing curves, which are normally performed on relatively dense bacterial populations (on the order of 10^7 cells per millilitre). Such high numbers ensure substantial heterogeneity in the physiological conditions of each bacterial cell, so different antibiotic actions are expected to apply in a population of cells with different ages and physiological states.

What pharmacodynamics tells us

What does the relationship between the concentration of antibiotics and the rate of growth and death of bacteria (that is, pharmacodynamics) tell us about how antibiotics do their bacteriostatic and bactericidal actions? As can be seen in FIG. 1, antibiotics differ considerably in the rates at which they kill bacteria. Although the drug dose, relative to the minimum inhibitory concentration, to which these

growing populations of *Staphylococcus aureus* are exposed (10 times the minimum inhibitory concentration) is the same for the nine drugs, the rates at which the viable cell densities decline (that is, the rates at which the bacteria are killed) differ considerably among these drugs. Antibiotics that are deemed bacteriostatic kill at low rates, whereas those deemed bactericidal kill at higher but very different rates. The rates at which oxacillin and vancomycin kill during the 8 hours of the experiment are not much greater than those of the bacteriostatic antibiotics. The rates of decline in the density of *S. aureus* exposed to gentamicin, daptomycin, ciprofloxacin and rifampin are not monotonic. In the case of rifampin, resistant mutants emerged. For the other three drugs, there is a levelling off in the kill rate, which can be attributed to persistence^{17,18}. The bacteria recovered from these time–kill experiments were as susceptible to these three drugs as their ancestors used to start the experiment.

There are a number of possible, but not mutually exclusive, explanations for these differences in killing rates, which we illustrate in FIG. 2. We believe the following explanations to be particularly relevant: (1) only free drug is active against the target bacteria, and protein binding of the drug decreases the rate of killing¹⁹; (2) there are structures (such as porins) and mechanisms facilitating drug uptake, but also barriers that prevent the drug from entering the cells²⁰; (3) the drug can be pumped out, so the concentration needed for killing takes longer to achieve^{21,22}; (4) the antibiotics with weak target-binding affinity will take longer to achieve the doses necessary for killing than those with greater affinity²³; (5) the targeted function might increase in the presence of the drug, thereby compensating for the inhibition by the drug²⁴; (6) the target function corresponds to the build-up of a cellular structure with slow turnover, which increases the amount of time for the antibiotic to kill^{25,26}; (7) the cells repair the damage produced by the antibiotics at rates that differ between drugs²⁷; (8) the damaged bacteria have inducible antibiotic-deactivating mechanisms²⁸; (9) the bacteria use alternative metabolic pathways that, to some extent, bypass those inhibited by the antibiotic^{29,30}; (10) antibiotics differ in the extent to which they induce reactive oxygen species (ROS; deleterious) or SOS (potentially protective) responses and thereby the rate at which they kill the exposed bacteria^{31–34}; (11) members of the antibiotic-exposed populations are either

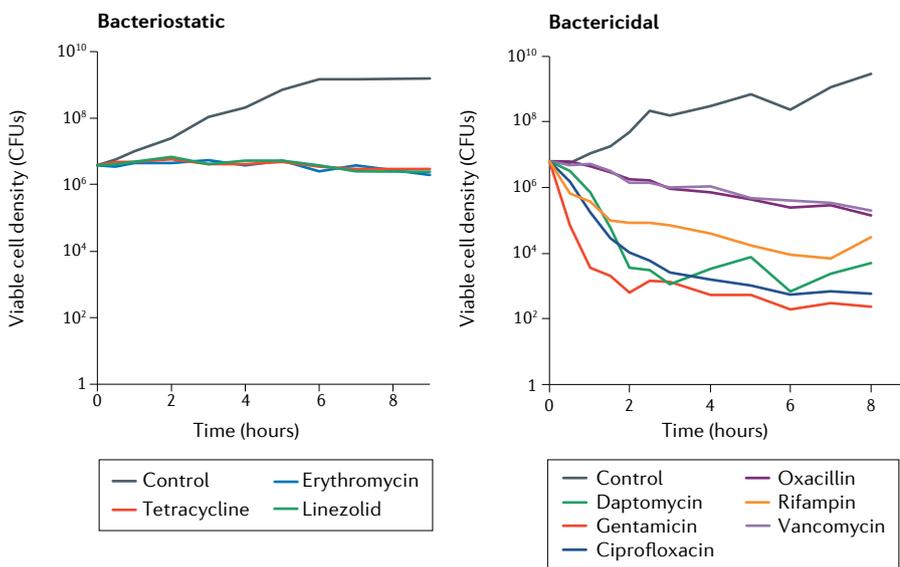

Fig. 1 | **Killing rates of different antibiotics.** The findings of time–kill experiments measured as changes in the viable cell density of *Staphylococcus aureus* Newman exposed to 10 times the minimum inhibitory concentration of nine different antibiotics in Mueller–Hinton II medium at 37 °C with aeration are shown. Bacteriostatic antibiotics (left) stop growth and colony-forming units (CFUs) remain stable. By contrast, bactericidal antibiotics (right) kill bacteria and thus the CFUs drop. Of note, a resistant mutant emerged in the culture treated with rifampin, leading to resumed growth at the end of the experiment.

not replicating or are replicating slowly, and as such are killed at lower rates than the more active members of the population or their death is delayed; (12) the antibiotics produce a kind of 'stationary phase' by activating the general RpoS-mediated stringent response³⁵. Notably, under very effective 'death-delaying conditions', before the point of no return is reached, it would be difficult to determine whether a cell is in the process of dying. However, when this point of no return is surpassed, the last resources are invested in programmed cell death, and the bacterium induces its own lysis and DNA degradation (apoptosis)³⁶.

Although it is convenient for investigators to separately consider the pharmacodynamics of the interaction of antibiotics and bacteria and the changes in antibiotic concentration with different therapeutic schedules (that is, the pharmacokinetics of the drug), bacteria do not have that luxury — the pharmacodynamics of antibiotic action is highly dependent on pharmacokinetics. On first consideration, it would seem the higher the concentration of the drug to which the bacteria are exposed, the higher the rate at which they are killed. This is the case for many antibiotics, but not for all. Commonly, but not universally, the rate at which bacteria are killed by antibiotics is proportional to the maximum rates of growth of their populations³⁷. One interpretation of this association is that death occurs when the demand for resources is great, and the amount of resources is severely limited by drug action. If only a fraction of the population of bacteria is in a 'susceptible mode' (replicating) at any time, the full bactericidal activity will be achieved only after prolonged periods of exposure (time-dependent killing, as is the case of β -lactams)³⁸. On the pharmacodynamics side, it may well be that the rate at which bacteria are killed depends on the multiplicity of targets simultaneously affected by antibiotic action, which provokes a chaotic and difficult-to-compensate chemical destructuring of the cell. This sort of mechanism has been invoked to explain the rapid killing (minutes) by most biocides, such as disinfectants or antiseptics^{39,40}. This rapid death by 'multiple targets' is also consistent with the frequent increase in the bactericidal effect measured in time-kill curves of synergistic antibiotic combinations⁴¹ or in phage-antibiotic combinations^{42,43}.

Towards a bactericidal coefficient?

Considering the plethora of factors contributing to the rates at which antibiotics kill bacteria, we can appreciate

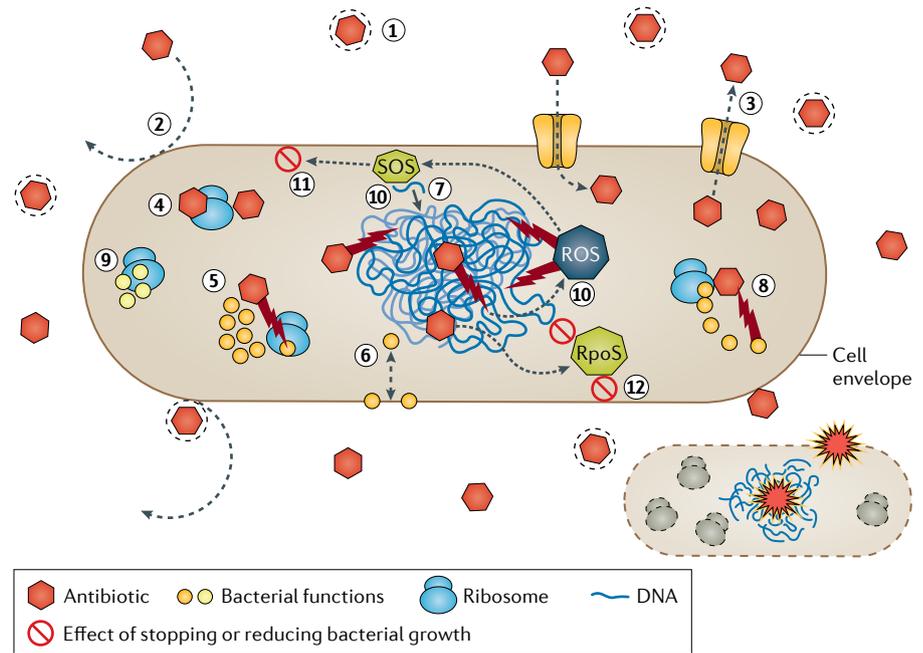

Fig. 2 | Factors influencing the bactericidal activity of antibiotics in a susceptible bacterial cell. Only free drug is active (1) and protein binding, for example to albumin or other plasma proteins, can reduce the level of available and thus active drug, as commonly observed for β -lactams. Uptake systems (such as porins) and barriers can prevent the drug from entering cells (2) or the drug is pumped out (3). Greater or weaker target-binding affinity also influences activity (4). The targeted function can also increase in the presence of the drug, thereby compensating for inhibition (5; for example, upregulation of RpoB by rifampin in mycobacteria). The target function involves the build-up of a cellular structure with slow turnover (for example, peptidoglycan), which increases the amount of time for the antibiotic to kill (6). The cells repair the damage produced by the drug (7), involving the SOS system. The bacteria have inducible antibiotic-deactivating mechanisms (8; for example, β -lactamases). The bacteria use alternative functions, bypassing those that are inhibited (9). Antibiotics differ in the extent to which they induce reactive oxygen species (ROS; deleterious) or SOS (potentially protective) responses (10). Low replication rates (involving the SOS system) reduce the killing activity (11). Activation of the RpoS-mediated stringent response produces a kind of 'stationary phase', reducing bactericidal potency (12). The two ultimate causes (bottom right) of a bactericidal effect are loss of spatial individuality by rupture of the limits with the environment (broken green line indicating disruption of the cell envelope) and loss of genetic individuality (broken blue line indicating disruption of the genome).

the difficulty of maintaining the tradition of classifying antibiotics as bactericidal and bacteriostatic. As noted in FIG. 1, at the concentration used, as measured by decline in colony-forming unit estimates of densities, all nine antibiotics examined killed *S. aureus*, although those deemed bacteriostatic killed at a lower rate than those considered bactericidal. Moreover, the rate at which a bacteriostatic antibiotic kills one species of bacteria, for example, *Escherichia coli*, can be markedly less than the rate at which it kills another species, for example, *Campylobacter jejuni*³. A possibility for dealing with this conceptual challenge is to attribute a bactericidal coefficient to each pair of antibiotic and bacterial species, considering the amount of killing at a given antibiotic concentration and time in established standardized conditions. This view originated in the

field of disinfectants (phenol coefficient, a measure of the bactericidal activity of a chemical compound in relation to phenol), and the calculation of 'specific bactericidal activities' (SBA method) is supported by the National Committee for Clinical Laboratory Standards^{44–46} but we are urging for the updating of such an approach⁴⁷.

How bacteria die

Death by exogenous disruption of cell envelopes. Cell envelopes are the hallmark of cellular individuality, the limit between the 'self' and 'non-self'. Many antimicrobial agents kill cells by direct disruption of cell envelopes⁴⁸. Of course, mechanical disruption of these envelopes by grinding, abrasion, high-pressure carbon dioxide or passing them through a narrow valve under high pressure (similar to a French press), ultrasonication and cavitation produces

rapid bacterial death⁴⁹. Other physical destructuring methods include use of dry ice with ethanol, boiling, osmotic or hydrostatic pressure and extreme pH values.

Chemical disruptors of cell envelopes include detergents, biocides, halogens and toxic gases⁵⁰. More similar to therapeutic antimicrobials are cell wall-destroying enzymes, bacteriocins and antimicrobial peptides, including host defence peptides of insects, reptiles or higher animals (for example, cecropins, magainins and defensins). These agents rapidly kill bacteria by producing holes in their envelopes (particularly the cellular membrane). A number of antibiotics that are used clinically, such as the cyclic peptides (polymyxin B and colistin) and lipopeptides (telavancin and daptomycin), kill by disrupting cell membranes. Similarly to that of detergents, the killing action of these agents may be better described as 'physical' rather than biological. At low concentrations of these agents, bacteria can compensate or repair the resulting damage and they can replicate at a rate that exceeds the killing rate.

Death by endogenous disruption of cell envelopes. Bacteria can commit suicide by disrupting their cell envelopes, leading to stiffness, strength loss and osmotic lysis. Autolysins, first studied in *Streptococcus pneumoniae*, are enzymes that degrade the peptidoglycan (cell wall) substrate and include glycosidases (muramidases, as LytA, lysozymes, glucosaminidases and transglycosylases), amidases and endopeptidases^{51,52}. The *cidABC* and *lrgAB* operons of *S. aureus* have been shown to influence bacterial death by post-translational regulation of peptidoglycan hydrolase activity⁵³. In all these cases, as well as in *E. coli*, β -lactams trigger autolysin release by disturbing the balance between peptidoglycan synthesis and hydrolysis, which is necessary for growth of the cell wall⁵⁴. Bacterial growth requires constant synthesis and turnover of the cell wall to insert new molecules, and the latter process relies on peptidoglycan cleavage enzymes, including glycosidases, amidases and endopeptidases⁵⁵. The same enzymes can produce lethal damage — the physiology of growth can be converted into the physiology of death.

The effect of autolytic enzymes seems to depend on teichoic acids in Gram-positive bacteria (at least in *S. pneumoniae*) and on lipopolysaccharides (LPS) in Gram-negative bacteria. The mechanism

of antibiotic induction of autolysins, as shown in *S. pneumoniae*, is based on the sequestration of the major autolysin LytA by membrane-bound lipoteichoic acids. In mutant *Bacillus subtilis* strains, in which teichoic acid–autolysin binding is altered by reduction of positively charged D-alanine esters in teichoic acids, autolysis is increased under β -lactam exposure⁵⁶. In *S. pneumoniae*, the availability of precursors and products of teichoic acids regulates the protease FtsH, influencing the balance between lipid membrane-associated teichoic acids and cell wall (peptidoglycan)-associated teichoic acids. Teichoic acid polymers can account for more than 60% of the mass of the Gram-positive cell wall⁵⁷. Under penicillin (a β -lactam) exposure (or prolonged stationary phase), FtsH degrades the lipid membrane-associated teichoic acid synthase TacL, leading to a short circuit in the normal teichoic acid balancing mechanism, favouring synthesis of cell wall-associated teichoic acids, which stimulates cell wall-destructive LytA activity, ending in cell lysis⁵⁸.

In Gram-negative bacteria, LPS in the outer membrane is the functional equivalent of the lipid membrane-associated teichoic acids in Gram-positive bacteria. In this case, the protease FtsH alter the turnover of LpxC, an essential enzyme for virtually all Gram-negative bacteria, which is involved in the first step of LPS biosynthesis, formation of lipid A⁵⁹. Similarly to FtsH in *S. pneumoniae*, FtsH in Gram-negative bacteria is regulated by the availability of precursors and products of the LPS synthetic pathway, including acyl-acyl carrier protein (acyl-ACP) precursors. Acyl-ACP accumulation probably correlates with a decrease in fatty acid synthesis in *S. aureus* and also in *E. coli*, as in vivo data are consistent with acyl-ACP targeting the same two proteins in both species^{59,60}.

In *E. coli*, the outer membrane LPS and the cell membrane phospholipid synthesis pathways compete for fatty acids⁶¹, leading to a destabilization of the outer membrane (less LPS). It should be remembered that the maintenance of the outer membrane integrity in Gram-negative bacteria is probably as important as the maintenance of the integrity of the cell wall, and its failure produces blebbing and killing⁶². In summary, the viability of the cell depends on a balanced synthesis of membrane phospholipids, fatty acids and cell wall constituents⁶³, and this coordination is altered by β -lactam exposure.

However, autolysis can also occur without specific induction of autolysins but rather as

a consequence of disbalance (uncoupling) between cell wall synthesis and degradation, owing to lack of control of peptidoglycan hydrolase turnover, typically involving low molecular weight penicillin-binding proteins that function as peptidoglycan-binding peptidases in *E. coli*^{64–66}.

How endogenous mechanisms can degrade the cytoplasmic membrane is less clear. Aminoglycosides interact with ribosomes, leading to production of mistranslated proteins. These proteins are misassembled in the membrane and are rapidly degraded, which contributes to bacterial killing^{67,68}. Degradation of misassembled membrane proteins is the result of a proteolytic 'quality control' system, which includes the membrane-integrated protease FtsH⁶⁹. Other ATP-dependent AAA+ proteases, including ClpP and the Lon proteases, which are present in many bacterial species, are also involved in the proteolysis of defective and misfolded proteins. As in the case for the cell wall, a disbalance in physiological proteolytic processes of the cell might result in membrane alteration and cell death^{70,71}.

As described in the following section, antibiotics might promote the formation of superoxides, leading to the oxydation of cysteine and methionine, resulting in protein damage. In other words, we can consider the replacement of senescent or damaged proteins as a requirement for maintaining life^{72,73}. An intriguing possibility that we believe is worthy of further exploration is a lethal threshold, a minimum rate of protein synthesis that bacteria require to repair or compensate structural damage. In the absence of structural repair, bacteria are killed⁷⁴.

Death by irreversible DNA damage.

Similarly to the disruption of cellular membranes, the disruption of DNA integrity is a marker of the loss of individuality. Endogenous cellular mechanisms damage DNA integrity, which can be the result of a stress response that induces the production of ROS (see earlier), reactive nitrogen species, reactive carbonyl species, lipid peroxidation products and endonucleases. Of course, external conditions can also damage cellular DNA, including UV light, ionizing radiation and genotoxic chemicals.

A number of antibiotics directly cause DNA breaks, such as bleomycin. Also, exposure to fluoroquinolones results in DNA breaks⁷⁵. Extensive DNA damage can induce a special mode of cell death. Single-stranded DNA resulting from damage triggers the protein RecA, which is involved

in the inactivation of LexA. LexA is a repressor of SOS response genes, and its inactivation leads to a cascade of events resulting in an alteration of the cellular membrane and DNA fragmentation. LexA is one of the most over-represented transcriptional regulators following fluoroquinolones treatment⁷⁶. DNA double-strand breaks can also be produced by antibiotic exposure and are potentially more lethal than single-strand breaks. A major inducer of the SOS response are ROS, producing DNA double-breaks. Their (not necessarily entirely successful) repair involves the RecBCD system, comprising a helicase that unwinds DNA strands and a nuclease that makes single-stranded nicks⁷⁷.

Probably the main driver leading to double-strand breaks is 8-oxo-2'-deoxyguanosine, which is produced by oxidation of precursor deoxyguanosine triphosphate and causes breaks in conjugation with MutY and MutM, proteins involved in DNA mismatch repair⁷⁸. As previously stated, it has been proposed that some bactericidal antibiotics ultimately kill bacteria by generating DNA double-strand breaks; chemicals producing breaks are synergistic with these antibiotics⁷⁹, and thus it can be expected that a shortage of protein synthesis might reduce repair functions, contributing to cell death⁷⁴. However, this effect is not always apparent in studies using combinations of protein-inhibiting drugs with DNA-damaging antimicrobials or chemical mutagens^{79,80}. Perhaps sequential rather than simultaneous exposure of DNA breaking and protein synthesis-inhibiting drugs would be a more effective way to use combinations of these antibiotics with these different modes of action.

It may well be that antibiotics that drive bacteria into an unspecific stress status mimic other conditions as oligothropy or starvation reduce the viability of bacteria by reducing the availability of nutrients required for essential energy-consuming functions, including DNA repair⁸¹. Certainly, *E. coli* has excess capacity for DNA repair, which compensates DNA damage from nutritional stress⁸². Perhaps exposure to DNA-breaking antibiotics can surpass this repair capacity.

A paradox that is observed across all fields of biology (including human infections, such as sepsis) is that the very same mechanisms responsible for physiological adaptation, defence and damage repair on crossing a threshold promote death⁸³. In this interpretation, some antibiotics kill by generating an irreversible cascade of events; for example, chromosomal lesions trigger the production

of ROS, which damages DNA, which in turn triggers the release of SOS response products intending to rescue the cell from death, but (not fully demonstrated) under high cytotoxicity could lead to destabilization of homeostasis, including iron-sulfur clusters, eventually increasing ROS levels further, resulting in more chromosomal breaks.

Bacteriostatic killing?

Is there a unique mechanism by which antibiotics prevent the replication of bacteria? A few years ago, along with other colleagues, we presented a hypothesis for how ribosome-targeting antibiotics that are deemed bacteriostatic not only prevent the replication of bacteria but might also be lethal³. In accord with our hypothesis, these drugs tie up enough ribosomes for cells not to be able to synthesize enough essential enzymes and other proteins required for replication or to ensure the healthy turnover of envelope components, including the most frequently transcribed proteins in the cell, ribosome proteins and membrane lipoproteins⁸⁴. As predicted by the model on which this 'numbers game' hypothesis was based, as the number of ribosomes is reduced, ribosome-targeting antibiotics will become increasingly bactericidal. Two lines of evidence were presented in support of this hypothesis, both of which were based on the number of ribosomal RNA (*rrn*) operons. *E. coli* strains with deletions of five or six of the seven *rrn* operons⁸⁵ were killed at a higher rate by azithromycin, chloramphenicol and tetracycline than the ancestral MG1655 strain or strains with more than two *rrn* operons. In *C. jejuni*, which has three *rrn* operons rather than seven as in *E. coli*, chloramphenicol and azithromycin are bactericidal rather than bacteriostatic as they are for *E. coli*³.

These results suggest that a low number of functional ribosomes might lead to a kind of lethal protein synthesis threshold. But we restrained ourselves from asserting that crossing this threshold is the ultimate mechanism by which these ribosome-targeting 'bacteriostatic' antibiotics kill bacteria. As mentioned already, shortage in key proteins involved in the cellular envelope structure might result in killing, but the association with the quantity of these proteins, or the number of active ribosomes, remains to be demonstrated.

A general killing mechanism?

In 2007, a then graduate student, Michael Kohanski, working with James Collins, presented a general hypothesis for how

different bactericidal antibiotics kill both Gram-positive and Gram-negative bacteria and evidence in support of that hypothesis. In accord with that hypothesis, these drugs stimulate the production of highly deleterious hydroxyl radicals, which kill bacteria by oxidative damage, inhibit the tricarboxylic acid cycle, transiently deplete NADH, destabilize iron-sulfur clusters and stimulate the Fenton reaction, resulting in lethal DNA breaks⁸⁶. In 2013, a series of articles were published pointing out the limitations of the experiments on which Kohanski and colleagues³² based their hypothesis that bactericidal antibiotics work through a common cell death mechanism involving ROS⁸⁷⁻⁸⁹. These authors did not present alternative mechanisms for the bactericidal activity of antibiotics.

This is not a forum to rant on about the details of the experiments performed in these studies and the inferences drawn. It is, however, useful to consider what came out of the ROS 'debate' in respect to our understanding of the ultimate mechanism responsible for how antibiotics kill bacteria. To wit, the debate is a compelling argument that there is not a unique mechanism by which antibiotics kill bacteria. In the years since the publication of the article by Kohanski and colleagues³², there have been a number of studies confirming that ROS have an important role in antibiotic-mediated killing of bacteria. These studies present evidence that ROS are frequently synergistic in the killing process with the damage directly caused by the antibiotic in the primary target, and dependent on the background state of cells already stressed by the antibiotic^{90,91}. As suggested by Yang and colleagues⁴⁷, this killing is not simply a matter of how the drugs act on their targets but is rather the result of an array of downstream consequences of the effects of the drug on that target. As indicated in a recent study by Hong and colleagues³⁴, ROS do indeed have a role in those downstream processes.

Specific antibiotics

In the following sections, we separately consider antibiotics of six classes, what is known, what has been postulated and what should be known about the ultimate mechanisms by which they kill bacteria. See FIG. 3 for a graphic summary of what follows.

Aminoglycosides. The confidence of clinicians in aminoglycoside therapy is commonly based on the known strong bactericidal effect of these drugs. Although a great deal is known about the proximal

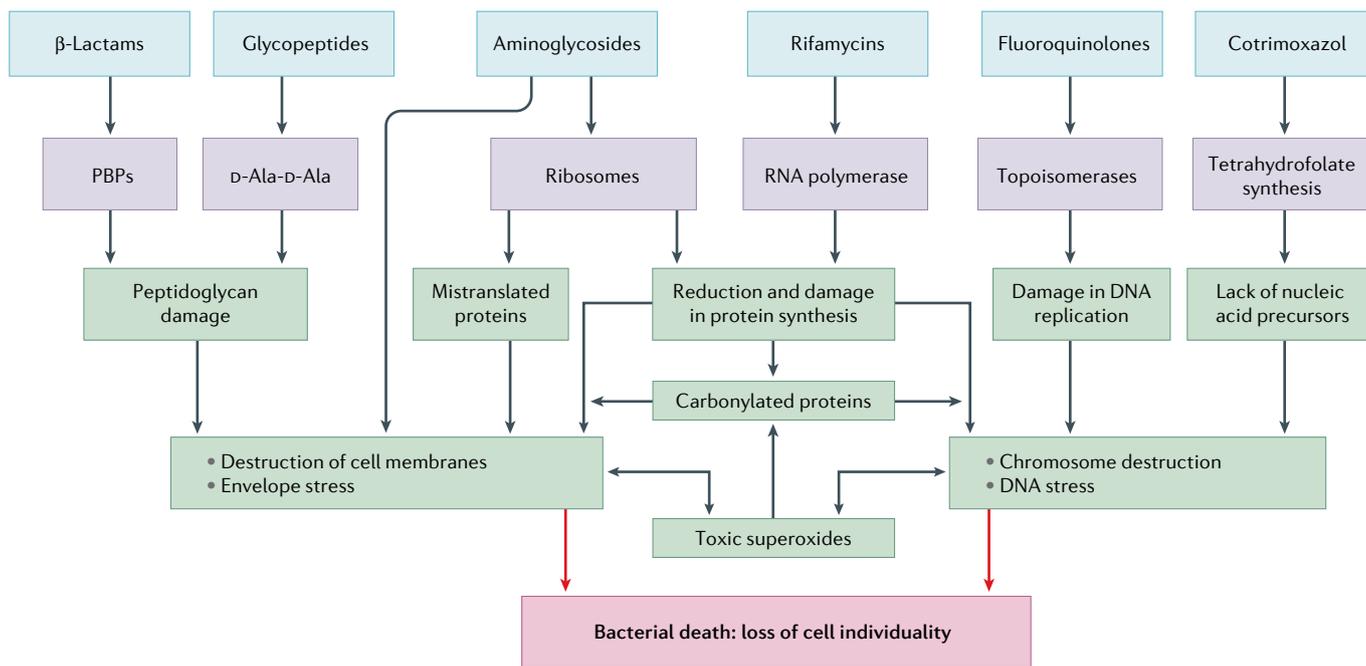

Fig. 3 | **Successive steps in the process of bacterial killing by antibiotics from six families.** These drugs (blue) directly interact with their targets (purple), which results in structural damage and/or quantitative or qualitative deficiencies of essential cell components. These changes, in turn, lead to envelope stress, DNA damage and/or the production of an excess of reactive oxygen species, which further contribute to the destructuring of cell membranes and nucleic acids. The net effect of these different processes (green) is the ultimate mechanism responsible for the loss of the cell's individuality, its death (red).

mechanism of action of aminoglycosides^{92,93}, no widely accepted or supported hypothesis exists so far for the ultimate mechanism by which these drugs kill bacteria. Three not mutually exclusive hypotheses stand out. A fourth hypothesis, death by superoxides, applies to all bactericidal antibiotics and will be considered separately.

The most commonly offered explanation for the bactericidal action of this class of drugs is that the ribosome–aminoglycoside interactions, mediated by the number and basicity of amino groups in the drug, give rise to toxic mistranslated proteins, which kill by increasing the permeability of the cell membrane⁹⁴. However, to our knowledge, these toxic proteins have not been isolated, and how they actually kill remains undemonstrated. It is also unclear why these postulated products of mistranslation are not destroyed by the proteases that usually remove mistranslated and misfolded proteins. On the other hand, in opposition of the toxic mistranslated protein hypothesis as the unique mechanism of killing by these drugs is the observation that killing occurs in the absence of aminoglycoside–ribosome binding, as happens with gentamicin in ribosomal 1041A>G mutants that have a single *rrn* operon⁹⁵ (B.R.L. and F.B., unpublished observations) and in the presence of the antibiotic resistance gene *armA*, encoding a 16S ribosomal RNA

guanine 1405-*N*⁷-methyltransferase⁹⁶. There is also a pharmacodynamic observation consistent with the toxic mistranslated protein hypothesis. In accord with this hypothesis, the rate of ribosome binding, and thereby the abundance of toxic proteins generated by mistranslation, should be proportional to the growth rate of the target population and the number of ribosomes, which indeed has been observed⁹⁷. However, some observations question the uniqueness of the toxic mistranslated protein mechanism explaining the bactericidal effect of aminoglycosides. Most importantly, gentamicin can kill *E. coli* and *S. aureus* in the stationary phase, when the number of ribosomes is minimal³⁵, and is more bactericidal in *E. coli* variants with a reduced number of *rrn* operons³. Collectively, these observations suggest a ribosome-independent (but not alternative) mechanism by which aminoglycosides kill bacteria.

Ribosome-independent killing by aminoglycosides involves direct killing by 'surface action'. The polycationic aminoglycoside molecules replace Mg²⁺ cations and thus destabilize key lipid structures of the outer membrane^{92,98–101}. After aminoglycoside exposure, potassium and intracellular molecules such as nucleotides leak from the bacterial cell immediately, certainly no later than

protein synthesis inhibitory effects^{35,92,102}. Besides, aminoglycoside exposure increases alarmone levels, resulting in increased membrane damage¹⁰³. Recent observations indicate that gentamicin at high concentrations can exert bactericidal activity on ribosomal 1041A>G resistant mutants (B.R.L., I. McCall and F.B., unpublished observations).

As stated before, a direct effect of aminoglycosides on the bacterial cell membrane is not incompatible with the need for ribosomal interaction. Binding to the ribosome triggers a massive secondary, energy-dependent uptake of aminoglycosides¹⁰⁴. This uptake will produce a 'cationic disturbance' of the membrane integrity and thereby kill without further involvement of ribosomes.

The quinolones. Fluoroquinolones bind to DNA gyrase and topoisomerase IV, leading to the formation of stable drug–enzyme–DNA complexes that block DNA replication and result in DNA double-strand breaks¹⁰⁵. Recombination and excision repair is involved in the repair of quinolone-damaged DNA, but continuous induction of these systems in response to exposure to the drug triggers the SOS response^{31,106}. Initially, the quinolone–gyrase–DNA complexes are unstable, and bacteria can recover in the absence of quinolone exposure.

However, if exposure is maintained, the complexes become stable, the SOS response continues and when a threshold is crossed, the death process becomes irreversible, even in the absence of the drug^{34,107}.

The activity of ciprofloxacin decreases when bacteria reduce their growth rates¹⁰⁸. This effect might contribute to explaining the biphasic dose response of most quinolones, producing a single concentration of maximum kill. The optimal bactericidal concentration probably depends on the SOS response, the formation of superoxides and DNA breaks. Concentrations higher than the optimal bactericidal concentration provoke an immediate SOS-independent inhibition of respiration and growth, with decreased ROS production and less death¹⁰⁸. Conversely, at the optimal bactericidal concentration, SOS-derived apoptosis-like death occurs. This pathway depends on RecA and LexA, resulting in cell death associated with membrane depolarization and ROS-induced DNA fragmentation⁸³. In summary, ultimate death by quinolones occurs by the disintegration of DNA mediated by ROS³⁴.

Rifamycins. The target of rifampin (and, in general, rifamycins) is the product of the *rpoB* gene, the DNA-dependent RNA polymerase. The drug strongly binds to the β -subunit of the core enzyme, thereby inhibiting initiation of transcription; that is, preventing effective protein synthesis¹⁰⁹. On first consideration, it may seem that inhibition of protein synthesis is not sufficient to provide rapid killing. However, in practice, rifamycins are considered to have an early bactericidal effect, not only in *S. aureus* (FIG. 1) and *E. coli*, but even in slowly growing bacteria such as *Mycobacterium tuberculosis*. In addition, the killing effect of rifampin is concentration dependent^{10,110}. High rifampin concentrations can even kill bacteria with some types of resistance mutations in the *rpoB* gene¹¹¹. By targeting RNA polymerases, rifamycins affect both translation and transcription, which together ensure the coordination of transcriptional activity to the translational needs under various growth rates^{112,113}. An interesting question is whether the inhibition of transcription might produce lethal effects independently from blocking protein synthesis. A classic transcription inhibitor is the toxin MazF, a component of the stress-induced MazF–MazE toxin–antitoxin machinery. In the absence of the antitoxin MazE, MazF inhibits protein

synthesis by cleaving mRNA, resulting in later death¹¹⁴. What are the causes of death? It has been suggested that there are a group of mRNAs that are resistant to cleavage by MazF, encoding ‘death proteins’, some of which damage cell envelopes¹¹⁵. A similar mechanism of death can be suggested for rifampin, which also selectively affects the transcription of different genes¹¹⁶. It is possible that rifampin, similarly to ribosome-binding antibiotics, reshapes the cellular proteome rather than just blocking global protein synthesis^{117,118}, but both effects might be synergistic for killing, particularly in species with a low number of *rrn* operons³. Rifamycins do not stimulate the production of hydroxyl radical production, which could contribute to cell death³².

β -Lactam antibiotics. β -Lactams target penicillin-binding proteins involved in the biogenesis of peptidoglycan¹¹⁹. There is a clear correlation between bacterial growth rate, needs of peptidoglycan biogenesis and cell lysis induced by β -lactams³⁷. Lysis requires functional assembly of the divisome, the cell division machinery¹²⁰, suggesting that lysis specifically occurs when the cell is ready for division¹²¹. Why is the loss of cell wall integrity and lysis the result of reduced peptidoglycan biogenesis? The traditional answer is induction of peptidoglycan autolysins¹²² or simply that these lysins continue their activity without compensation by biogenesis (see earlier). More recently, it has been proposed that inhibition of penicillin-binding proteins by β -lactams produces a deleterious ‘futile cycle’ of metabolic pathways involved in peptidoglycan synthesis and degradation running simultaneously in opposite directions and promoting deintegration and lysis¹²³. Besides, disruption of cell envelope integrity, leading to bubbling and ‘explosion’ of the cell, particularly in Gram-negative bacteria, is probably triggered by lacking coordination of the multicomponent machinery that links the growth of the different envelope layers, and involves sensing of unassembled outer membrane proteins and LPS in the periplasm¹²³. The possibility of biophysical shearing of different layers, owing to disbalance between cell wall and membrane growth^{124–126} and resulting in cell lysis, cannot be discarded and is worth further and deeper consideration. Finally, there is evidence that β -lactam antibiotics are bactericidal through DNA damage by ROS^{34,127}.

Vancomycin. Vancomycin is a lipophilic cationic antibiotic that inhibits synthesis of the bacterial cell wall by binding to the dipeptide terminus D-Ala-D-Ala of peptidoglycan pentapeptide precursors, preventing subsequent transpeptidation and transglycosylation and thus peptidoglycan crosslinking¹²⁸. Deficient crosslinking of the long sugar backbone chains of *N*-acetylglucosamine/*N*-acetylmuramic chains results weakens the cell to osmotic damage, leading to cell disintegration. Similarly, this effect explains why vancomycin-exposed cells are much more sensitive to ultrasound²⁵. In *S. aureus*, the bactericidal effect of vancomycin is generally weaker than that of most β -lactams¹²⁹. This difference can be explained by the huge size of vancomycin (1,450 Da) compared with oxacillin (401 Da), which impedes diffusion through the cell wall, which is also supported by the finding that thicker peptidoglycan reduces the effect of vancomycin¹³⁰. Consistently, time–kill curves show that varying the concentration of vancomycin has no effect on the rate or extent of bacterial killing¹³¹, probably owing to vancomycin clogging in the cell wall. Independently from the membrane–cell wall shearing effect (see the section “ β -Lactam antibiotics”), direct membrane damage can probably be excluded, as vancomycin does not act on protoplasts or *Mycoplasma* spp., both of which have no cell wall. Superoxide anions might also be involved in the bactericidal activity of vancomycin in *Enterococcus* spp. and *Staphylococcus* spp.¹³².

Sulfonamides and trimethoprim.

Sulfonamides and trimethoprim are bacteriostatic, but the combination is synergistic, and has a strongly bactericidal effect¹³³. The two drugs inhibit two sequential steps in tetrahydrofolate synthesis (required for nucleotide synthesis), but this cannot explain the bactericidal synergism. The synergy is more likely due to the disruption of a previously unrecognized metabolic feedback loop by trimethoprim, which results in cyclic mutual potentiation of the effects of the two drugs, leading to amplified depletion of tetrahydrofolate, an essential cofactor in the biosynthesis of thymine^{127,134}. However, the ultimate mechanism of killing by thymine deficiency (the classic ‘thymineless killing’) remains elusive; the deprivation of nutritional requirements normally has a biostatic, but not lethal, effect^{135,136}. Most probably, thymine starvation promotes cell killing by ROS-mediated DNA damage³⁴.

Conclusion and final remarks

Surely, we would all love to have a unique, broadly supported hypothesis for how antibiotics kill bacteria; this is particularly so if we were the investigators responsible for providing that hypothesis. This is not the case; there is no a priori reason to expect that the same antibiotics targeting different species of susceptible bacteria would reach these ultimate (killing) effects by the same processes under different growth conditions. On the other, more positive, side, this Perspective suggests that antibiotics with markedly different structures, targets and effects on the structure and physiology of bacteria have proximate mechanisms of action that converge through different processes in the death of bacteria by physical or genetic destructuring, the ultimate effects (FIG. 3). Moreover, we believe that the links between proximate and ultimate mechanisms of the bactericidal and bacteriostatic actions can be elucidated for specific antibiotics and different species of bacteria under different growth conditions.

A multifactorial perspective of bacterial killing will be needed to fully understand how the effects of the primary antibiotic action on targets can be modulated, and eventually amplified, in the context of complex interactions and changes of cell metabolism, and general cellular responses, including ROS production, SOS induction and RpoS regulatory effects. Certainly many of these responses are sensitive to the environment, and therefore the bactericidal effect is expected to differ in various circumstances, bacterial species and lifestyles. A wide field of research is being opened.

But is it worth the effort? We know that bacteria are killed and/or prevented from replicating when exposed to antibiotics, and we know a great deal about the conditions under which these drugs have these bactericidal and bacteriostatic effects. Is this information, which is critical to the clinical applications of these drugs, not entirely sufficient? We suggest it is not. Elucidating how and when different antibiotics prevent the replication of bacteria and kill them is not just an academic exercise. This information will be useful for developing much-needed new antibiotics. It will also be helpful for designing protocols for the administration of existing antibiotics and combinations of antibiotics that are effective clinically, and at the same time minimize the likelihood of emergence and rise of resistance to these drugs in target bacteria and commensals and disturbance of the microbiota.

Acknowledgements

The authors are grateful to their awesome wives, Ros and Adriana, for putting up with them during this period of COVID-19 quarantine and supporting their playing fun games such as reviewing the literature and writing this Perspective.

They thank I. McCall for a careful reading of this manuscript, and J. Rodríguez-Beltrán for discussion about some critical concepts. This research was funded by grants from the U.S. National Institutes of General Medical Science (GM091875-17 and 1R35 GM136407-01) to B.R.L. and from the Regional Government of Madrid (InGeMICS- B2017/BMD-3691) and the Ramón Areces Foundation to the F.B. laboratory. The authors dedicate this Perspective to the memory of J. Acar¹³⁷, with whom they would have loved to have discussed the question of how antibiotics kill; from those conversations with Jacques, the authors know they would have had much more to tell you about the answer.

Author contributions

The authors contributed equally to all aspects of the article.

Competing interests

The authors declare no competing interests.

Peer review information

Nature Reviews Microbiology thanks the anonymous reviewer(s) for their contribution to the peer review of this work.
