The in-vitro effect of famotidine on SARS-CoV-2 proteases and virus replication

Madeline Loffredo^{1,6}, Hector Lucero^{1,6}, Da-Yuan Chen^{3,4}, Aoife O'Connell^{3,5}, Simon Bergqvist², Ahmad Munawar^{1,6}, Asanga Bandara^{1,6}, Steff De Graef^{1,7}, Stephen D. Weeks^{1,7}, Florian Douam^{3,5}, Mohsan Saeed^{3,4}✉ & Ali H. Munawar^{1,6,7}✉

The lack of coronavirus-specific antiviral drugs has instigated multiple drug repurposing studies to redirect previously approved medicines for the treatment of SARS-CoV-2, the coronavirus behind the ongoing COVID-19 pandemic. A recent, large-scale, retrospective clinical study showed that famotidine, when administered at a high dose to hospitalized COVID-19 patients, reduced the rates of intubation and mortality. A separate, patient-reported study associated famotidine use with improvements in mild to moderate symptoms such as cough and shortness of breath. While a prospective, multi-center clinical study is ongoing, two parallel in silico studies have proposed one of the two SARS-CoV-2 proteases, 3CL^{pro} or PL^{pro}, as potential molecular targets of famotidine activity; however, this remains to be experimentally validated. In this report, we systematically analyzed the effect of famotidine on viral proteases and virus replication. Leveraging a series of biophysical and enzymatic assays, we show that famotidine neither binds with nor inhibits the functions of 3CL^{pro} and PL^{pro}. Similarly, no direct antiviral activity of famotidine was observed at concentrations of up to 200 μ M, when tested against SARS-CoV-2 in two different cell lines, including a human cell line originating from lungs, a primary target of COVID-19. These results rule out famotidine as a direct-acting inhibitor of SARS-CoV-2 replication and warrant further investigation of its molecular mechanism of action in the context of COVID-19.

A large part of the current therapeutic discovery effort against the severe acute respiratory syndrome coronavirus 2 (SARS-CoV)-2 is focused on drug repurposing¹. Of such agents, only remdesivir has thus far shown clinical evidence of antiviral effect², while several others have not met their primary endpoints in various clinical studies^{3,4}. Recently, famotidine has gained attention as a therapeutic option against SARS-CoV-2, initially based on anecdotal evidence of its positive effects in COVID-19 patients in China. Famotidine (PEPCID*), a histamine-2 receptor (H2R) antagonist, is an FDA approved drug for the treatment of gastroesophageal reflux disease (GERD) and gastric ulcers⁵.

Earlier reports of the beneficial effect of famotidine in China were recently supported by a retrospective clinical study involving 1620 patients in the U.S., which noted that hospitalized COVID-19 patients receiving a total median dose of 136 mg famotidine, in oral or IV formulation once daily, for 6 days had a reduced risk of death or intubation⁶. Another study involving 10 non-hospitalized patients linked the use of high-dose oral famotidine (240 mg per day for a median of 11 days) with patient-reported improvements in symptoms such as shortness of breath and cough⁷. These two reports conclude that the use of high-dose famotidine may be associated with improvements in both mild and severe symptoms of COVID-19. While a large, multi-center clinical trial to confirm these observations is in progress, the mechanism by which famotidine purportedly improves the clinical outcomes in COVID-19 patients is unknown. In silico modeling and molecular docking studies have separately suggested either of the two SARS-CoV-2 proteases as potential targets of famotidine activity^{8,9}. In one computational study, Wu et. al. docked a library of approved drugs on to the available X-ray crystal structure of the 3-chymotrypsin-like protease (3CL^{pro}) of SARS-CoV-2, identifying famotidine as one of the drugs likely to

Figure 1. Effects of famotidine on PL^{pro} and 3CL^{pro} protease activity. *In-vitro* inhibition assays (IC₅₀) of PL^{pro} (a) and 3CL^{pro} (b) activity show that famotidine had no effect on either of the two SARS-CoV-2 proteases. IC₅₀ values represent inhibition of viral protease activity by control compounds (black) or famotidine (green) when tested at various concentrations. The initial slopes of protein catalytic activity were converted from RFU/min to $\mu\text{mole fluorophore/min}$. Values are mean $\pm$ standard deviation of triplicates. The compounds tested in this experiment neither quenched fluorescence nor produced auto-fluorescence.

act on the protease⁸. Other computational reports have predicted famotidine as an inhibitor of the Papain-like protease (PL^{pro}), a second SARS-CoV-2 protease⁹. Together, these studies have raised the prospect of a direct antiviral effect of famotidine on SARS-CoV-2 replication. While both proteins are attractive targets for SARS-CoV-2 drug development^{10–19}, there are at present no clinical-stage or approved drugs targeting either protein. The possibility of famotidine, an approved drug, acting on SARS-CoV-2 proteases is of significant clinical interest. In this *in-vitro* study, we performed an array of biochemical, biophysical, and antiviral experiments to test if famotidine is an effector of SARS-CoV-2 proteases and whether it inhibits virus replication in cultured cells.

Results

Famotidine is not an inhibitor of SARS-CoV-2 proteases. Processing of the SARS-CoV-2 polyprotein is critical to the generation of a functional virus replication complex^{11,18,20}. To carry out this essential proteolytic function, the SARS-CoV-2 genome encodes two cysteine proteases, called PL^{pro} and 3CL^{pro}¹⁸. Due to their critical roles in viral polyprotein processing and virus proliferation, both proteases are considered attractive targets for drug discovery^{10,11,13–17,21}. Since *in silico* docking studies have predicted these proteases as putative molecular targets of famotidine^{6,8,9}, we methodically investigated the effect of famotidine on the catalytic functions of each protease.

First, we developed an *in-vitro* activity assay of PL^{pro}. PL^{pro} is a protease domain found within the large multi-domain nsp3 protein encoded by SARS-CoV-2. While many coronaviruses encode two papain-like proteases, SARS-CoV, MERS-CoV and SARS-CoV-2 possess only one PL^{pro}, which processes the amino-terminal end of the viral polyprotein liberating nsp1, nsp2 and nsp3^{19,21}. Additionally, PL^{pro} deubiquitinates host cell proteins by cleaving the consensus motif of LXGG^{18,19} and is known to efficiently hydrolyze both diubiquitin and synthetic peptide substrates¹⁹. We leveraged the deubiquitinating property of PL^{pro} to set up a functional activity assay using ubiquitin-AMC, a fluorogenic substrate cleavable by PL^{pro}. Upon incubation with PL^{pro}, the ubiquitin is recognized and cleaved at the C-terminus to liberate the AMC (amido-4-methylcoumarin) fluorophore which results in increased fluorescence that is read using excitation and emission wavelengths of 355/460 nm. We assessed the ability of famotidine to inhibit the proteolytic activity of PL^{pro} at a broad range of drug concentrations vis-à-vis **compound 6**, a previously reported inhibitor of PL^{pro} activity²¹. Experimental conditions including protein and substrate concentrations, buffer composition, and assay kinetics were optimized using **compound 6**. While **compound 6** inhibited PL^{pro} activity with the expected low single-digit μM IC₅₀ values, famotidine showed no reduction in PL^{pro} activity in the titrated range of 0.01–200 μM (Fig. 1a).

We next tested whether famotidine can inhibit the enzymatic activity of 3CL^{pro}, the second protease encoded by the SARS-CoV-2 genome. This protein, also referred to as the main protease (M^{pro}) or nsp5, cleaves the viral polyprotein at 11 unique sites¹¹. This proteolytic activity generates multiple individual functional proteins required for the assembly of the SARS-CoV-2 replication/transcription complex, which drives viral genome replication²⁰. Owing to its central role in the coronavirus life cycle, 3CL^{pro} has received significant attention as a drug target resulting in the discovery of several potent inhibitors^{10,14,15,17}. Native 3CL^{pro} exists as a homodimer and requires dimerization for its proteolytic activity¹¹. The catalytic mechanism of 3CL^{pro} activity is typical of cysteine proteases, where the Cys-His catalytic dyad drives site-specific cleavage of substrates. We evaluated the enzymatic activity of 3CL^{pro} using a FRET-peptide substrate that quenched fluorescence in its intact form, however, cleavage of the peptide substrate by 3CL^{pro} produced fluorescence that could be measured at the excitation/emission wavelengths of 490/535 nm. The inclusion of **ML188**, a previously reported 3CL^{pro} inhibitor served as a control, also aiding assay setup and optimization. Results of the FRET assay for various **ML188** and famotidine concentrations are shown in Fig. 1b. Both compounds were tested between a range of 0.01–200 μM . While **ML188** produced a dose-dependent inhibition of 3CL^{pro} activity with an expected IC₅₀ of 2.4 μM , famotidine did not inhibit 3CL^{pro} activity.

Figure 2. Binding of famotidine to PL^{pro} and 3CL^{pro} analyzed by SPR. Soluble biotinylated PL^{pro} (a, b) and 3CL^{pro} (c, d) were immobilized on a neutravidin-coated sensor chip and a range of compound concentrations were injected with solvent (DMSO) corrections. Both, (a) *compound 6*, the known PL^{pro} inhibitor and (c) *ML188*, the 3CL^{pro} inhibitor displayed dose-dependent binding to PL^{pro} and 3CL^{pro}, respectively. Whereas, (b, d) no binding of famotidine was detected to either protein. The dissociation constant (K_d) values for the control compounds are shown in Table S1 (Supplementary Information).

When tested alone, neither famotidine nor the other tested compounds produced autofluorescence at the 355/460 nm and 490/535 nm wavelengths, respectively. These two experiments indicate that famotidine does not interfere with the catalytic activity of either of the two SARS-CoV-2 proteases.

Famotidine does not directly engage PL^{pro} or 3CL^{pro} of SARS-CoV-2. The function of many enzymes, such as proteases and kinases, can extend beyond their catalytic roles and includes a wide spectrum of non-catalytic activities such as allosteric regulation, scaffolding, protein–protein interactions, and protein–DNA interactions²². To rule out whether famotidine could bind away from the active site of the two viral proteases, and exert an effect through interference with non-proteolytic functions, we asked if famotidine is able to bind directly with either of the two SARS-CoV-2 proteases. For this, we employed two distinct biophysical techniques i.e. surface plasmon resonance (SPR) and differential scanning fluorimetry (DSF), that are routinely used to probe drug–protein engagement.

For our SPR studies, the biotinylated viral proteases were captured to a high density on sensor chips via neutravidin, permitting real-time detection of small-molecule binding to the target viral proteases. Engagement of the small-molecule compounds was recorded as an increase in dose-dependent response units (RU) during the assay. Experimental conditions including buffer composition and temperature were optimized using the control compounds prior to conducting the famotidine studies. The equilibrium dissociation constant (K_d) values were determined using both a kinetic analysis and fit to a binding isotherm of the dose response data (Fig. 2). The observed K_d values for the known 3CL^{pro} and PL^{pro} inhibitors (Supplementary Information Table S1) were consistent with the published IC₅₀ data^{14,21} indicating the robustness of our assay methodology. Under these

Figure 3. DSF assays of famotidine binding to PL^{pro} and 3CL^{pro}. Fluorescence-monitored thermal denaturation assay showing the melting curve (first-derivative of dissociation) for each of the two proteins (7 μ M) in the presence or absence of compounds (2.5 mM). (a) PL^{pro} melting curves for DMSO control (black), *compound 6* (green) and famotidine (red) show that while *compound 6* stabilizes the PL^{pro} ΔT_m by 6.6 $^{\circ}$ C, famotidine is unable to shift the ΔT_m . Similarly, in (b) while ML188 (green) stabilizes 3CL^{pro} ΔT_m by 5.3 $^{\circ}$ C, famotidine (red) does not shift the melting temperature of 3CL^{pro}. The values are mean $\pm$ standard deviation of three independent replicates.

optimized conditions, famotidine was not found to interact with either of the two viral proteases at concentration ranges of up to 100 μ M.

To validate the results obtained from our SPR analysis, we employed an orthogonal DSF assay. DSF is a fluorescence-monitored thermal denaturing technique in which the melting temperature (T_m) of a protein is tracked via fluorescence as the sample temperature is incrementally raised in the presence of a hydrophobic dye. Drug binding to its target protein is known to stabilize (or destabilize) protein structure resulting in a variation of T_m profiles in the absence or presence of a drug. DSF provides definitive confirmation of target engagement as the increase in thermal unfolding temperature (ΔT_m) is only achieved when the compounds bind to the folded state of the protein. The ΔT_m is proportional to the K_d of the interaction and concentration of the compound. We tested the ability of famotidine and the control inhibitors to alter the thermal stability profiles of PL^{pro} and 3CL^{pro}. An optimal signal profile was obtained with 7 μ M PL^{pro} or 3CL^{pro}. Both proteins were tested separately in the presence of DMSO (-ve control), their respective control inhibitors, and famotidine at concentrations of 1, 2.5 and 5 mM. In agreement with the SPR data, the control inhibitors produced a quantitative increase in observed T_m (Fig. 3). While *compound 6*, the known PL^{pro} inhibitor, stabilized PL^{pro} by a T_m shift of 6.6 $^{\circ}$ C (Fig. 3a), and ML188, the 3CL^{pro} inhibitor, produced a T_m shift of 5.3 $^{\circ}$ C (Fig. 3b), famotidine did not alter the T_m of either of the two viral proteases. Taken together, the biophysical data decisively rules out the possibility of famotidine exerting its effect on PL^{pro} or 3CL^{pro} through interference with catalytic or non-catalytic protein functions as it is unable to bind with either of the two proteases.

Famotidine does not inhibit SARS-CoV-2 replication in cultured cells. Having established that famotidine does not inhibit SARS-CoV-2 proteases, we investigated the ability of famotidine to block virus replication in cell culture. For this, we infected Vero E6 cells, a commonly used cell model of SARS-CoV-2 infection derived from the African green monkey kidney. Infection efficiency was quantified through multiple, orthogonal readouts, including quantitative real-time PCR (qRT-PCR), plaque formation, and immunofluorescence. Remdesivir inhibited viral replication with an estimated half-maximum inhibitory concentration (IC₅₀) value of 3.3 μ M, as determined by immunofluorescence (Fig. 4a). In contrast, famotidine did not produce any measurable inhibition at concentrations of up to 200 μ M at 72 h post infection. Similar results were obtained when viral replication was examined by infectious virion production using plaque formation assays or by quantifying viral RNA copy numbers in the cell culture medium using qRT-PCR (Supplementary Figures S1 and S2).

To confirm these results in a more physiologically relevant cell model of SARS-CoV-2 infection, we assessed the antiviral activity of famotidine in human lung A549 cells. These cells were engineered to express essential SARS-CoV-2 entry factors, ACE2 and TMPRSS2²³. The cells were infected with SARS-CoV-2 and cultured in the absence or presence of the control or test compounds. Virus replication (infection) efficiency was measured and reported as a function of compound concentration (Fig. 4). While remdesivir strongly inhibited virus replication in a dose-dependent manner with an IC₅₀ value of 0.43 μ M, famotidine had no measurable effect (Fig. 4b). Our results are consistent with previously reported studies in which remdesivir exerted a greater antiviral effect in human lung A549 cells than in Vero E6 cells²⁴. The fact that famotidine does not inhibit SARS-CoV-2 replication in the A549 cells which possess the serine protease TMPRSS2 also likely points to it having no effect on host proteases involved in viral entry.

In-parallel cytotoxicity assays, carried out in both Vero E6 and A549 cells, showed that famotidine was not toxic up to the highest tested concentrations of 200 μ M (Fig. 4). Remdesivir, on the other hand, exhibited dose-dependent cytotoxicity at higher concentrations, well above its IC₅₀. Together, these results show that famotidine

Figure 4. Antiviral activity of famotidine in Vero E6 and human lung A549 cells. Percent inhibition of SARS-CoV-2 replication and cytotoxicity are shown in the presence of a range of famotidine (top) and remdesivir (bottom) concentrations for (a) Vero E6 cells and (b) human lung A549 cells. Percent infection values (blue) represent the antiviral activity (IC_{50}) of the drug compounds and cell viability values (red) represent cytotoxicity (CC_{50}) of the drugs. Infection was assessed through quantitation of virus-treated cells that stained positive for the viral nucleocapsid protein, 72 h post infection. Cell viability of the corresponding compound concentrations on the cells was measured using the CellTiter-Glo assay. Values reported are mean $\pm$ standard deviation of triplicates.

does not inhibit SARS-CoV-2 replication in cultured cells and that its purported clinical benefit may be due to an alternative mechanism of action.

Discussion

Two *in silico* studies have separately predicted the 3CL^{pro} or PL^{pro} of SARS-CoV-2 as potential molecular targets of famotidine^{8,9}, implying that famotidine associated improvement in COVID-19 patients may be due to a direct antiviral mechanism of action⁶. Despite recent advances in computational techniques, there are several challenges associated with the use of molecular docking to predict protein–ligand interactions accurately. Some of these challenges arise from the flexibility of the target protein, lack of prior knowledge of drug-binding sites, and protonation states of target amino acids²⁵. While results obtained from molecular docking can serve as a basis for new hypotheses, experimental validation is needed. Our ligand-binding experiments using SPR and DSF did not support previous *in silico* predictions of direct binding between famotidine and SARS-CoV-2 proteases. We further used an array of experimental approaches to show that famotidine had no effect on SARS-CoV-2 protease function or generally on viral replication. It must be noted that since the clinical studies correlated putative clinical benefit with the use of higher doses of famotidine, we tested famotidine at significantly higher *in-vitro* concentrations than the peak plasma concentrations (0.5–2 μM) achieved in the blood of patients in both clinical studies^{6,7}. Our data strongly suggest that the probable clinical benefit of famotidine likely arises independently of an antiviral mechanism of action.

COVID-19 complications are associated with a severe pro-inflammatory response in the lungs of infected patients²⁶. The “cytokine storm” as a result of inflammation is a key pathognomonic feature of COVID-19 and the main contributor to respiratory failure and mortality²⁷. Severe COVID-19 cases are characterized by pulmonary infiltration and extensive pulmonary edema, causing exudation of inflammatory cells in the alveolar space, resulting in extensive pulmonary consolidation leading to pneumonia and adult respiratory distress syndrome (ARDS)^{28–31}. The results of the two famotidine-related COVID-19 clinical reports, when taken together^{6,7}, suggest that famotidine likely helps with mitigating moderate to severe respiratory symptoms ranging from shortness of breath to intubation. Our data does not rule out the possibility that famotidine related improvements in COVID-19 patients are through an anti-inflammatory action. For example, the development of the cytokine storm in COVID-19 patients is characterized by elevation of pro-inflammatory type I cytokines, which are secreted from a variety of cells such as polymorphonuclear cells, natural killer cells, and endothelial cells, etc²⁷.

It is therefore conceivable that famotidine-related benefit in managing respiratory symptoms may be due to an anti-inflammatory mechanism of action.

It is noteworthy that H2R, the established molecular target of famotidine, is involved in the activation of several mediators of the adaptive immune response, such as Th1 lymphocytes, which are implicated in pro-inflammatory cytokine production³². Histamine, the H2R ligand, also regulates bronchoconstriction, airway inflammation, and vasodilation³². Mast cells are a major source of histamine and their activation has been reported following viral infections of the respiratory tract^{33–35}. Therefore, Mast cells may represent an underappreciated source of pro-inflammatory cytokine release in COVID-19 patients³³. A better understanding of the role of the H2R pathway in COVID-19 will help elucidate the molecular details of how famotidine reduces the disease severity.

Our *in-vitro* study redirects the mechanism behind the potential beneficial effect of famotidine, away from an antiviral effect to likely an anti-inflammatory action in COVID-19 patients. Given that there is an ongoing randomized clinical trial (NCT04370262), our results may assist the investigators in reshaping their interventional study to include inflammation-related outcomes. Also, it should be noted that while famotidine is one of the relatively safer drugs, its use is not without risk^{36–38}, especially in elderly patients (a high-risk population for COVID-19), in which famotidine use has been associated with CNS complications³⁹. Provided the ongoing clinical trial yields promising results, further investigation of famotidine and its safety profile in different age brackets will be needed before the drug can be used, most likely as part of a combination therapy, for COVID-19 disease management.

Materials and methods

Compounds. Famotidine was acquired from Sigma Aldrich (Missouri, USA; cat. No. F6889). **Compound 6**, a previously reported inhibitor of SARS-CoV-2 PL^{pro} function²¹ was acquired from MedChem Express, Inc. (New Jersey, USA; cat. no. HY-17542). **ML188**, a compound with known 3CL^{pro} inhibitory activity¹⁵ was also acquired from MedChem Express, Inc. (cat. no. HY-136259). Similarly, remdesivir (cat. No. HY-104077) an inhibitor of SARS-CoV-2 replication² was purchased from the same vendor. All compounds were dissolved in 100% DMSO at 100 mM.

Cloning, expression, and protein purification. The complete sequences encoding 3CL^{pro} and residues 746–1060 of PL^{pro} (Wuhan-Hu-1 isolate, GenBank accession NC_045512) were cloned into a charge modified SUMO fusion expression vector, generated in-house. The fusion protein was expressed for 24 h in Rosetta-2 (DE3) pLysS at 18 °C in ZYP-5052 autoinducing media. Harvested cells were resuspended in 50 mM Hepes pH 7.5, containing 150 mM NaCl and lysed by sonication. The clarified supernatant was loaded onto a HiTrap HP SP column (Cytiva, Massachusetts, USA; cat. no. 17115201) and the target fusion protein was captured in a cation-exchange chromatography step and eluted using a NaCl gradient. SUMO hydrolase was added to the pooled fractions to liberate the target protein and the sample dialyzed against 20 mM Tris, 10% v/v glycerol, 5 mM DTT pH 7.0 overnight at 4 °C. The protein was reloaded on the HiTrap HP SP column to remove the SUMO protein and hydrolase in a subtractive step. The flow-through, containing 3CL^{pro} or PL^{pro} was further purified by anion exchange chromatography using a HiTrap HP Q column (Cytiva; cat. no. 17115401) employing a NaCl gradient to elute the protein. Pooled fractions were further purified by size exclusion chromatography in 20 mM Tris pH 7.4, 150 mM NaCl and 5 mM DTT. The final protein was concentrated to 4 mg/mL for PL^{pro} and 5 mg/mL for 3CL^{pro} and flash frozen in aliquots.

In-vitro viral enzyme assays. *PL^{pro} proteolytic activity assay using ubiquitin-AMC.* PL^{pro} activity was measured in a 384 well plate format (Corning #3574) in a kinetic assay using the fluorogenic substrate Ubiquitin-AMC (Boston Biochem, Inc. Massachusetts, USA; cat. No. U-550) with excitation and emission wavelengths of Ex355nm/Em:460 nm. The protocol followed previously reported conditions with minor modifications^{13,16}. Fluorescence was monitored at 25 °C, every 5 min for 50 min in a Victor X5 (Perkin Elmer) multimode plate reader. Optimal enzyme and substrate concentrations were found to be 550 nM PL^{pro} titrating the substrate in the range of 0.2 – 3 μM. The assay buffer (20 μL) contained 25 mM HEPES pH 7.5, 100 mM NaCl, 0.1 mg/ml BSA, and 550 nM PL^{pro}. The test inhibitor, famotidine and the PL^{pro} control inhibitor (**compound 6**) were both titrated in the concentration range of 0.01 μM – 200 μM. Compounds were incubated with the enzyme in the plate for 30 min at 25 °C before the reaction was started by the addition of 1 μM Ub-AMC. All samples were run in triplicates and their initial slopes were converted from relative fluorescence units (RFU)/min to μmol AMC/min using an AMC standard curve and plotted against compound concentrations tested.

3CL^{pro} proteolytic activity assay. 3CL^{pro} activity was assayed in a 384 well plate using the 3CL^{pro} FRET substrate (AnaSpec, Inc. California, USA; cat. no. AS-65599) with excitation and emission wavelengths of Ex: 490 nm/Em: 535 nm. A previously reported protocol was used with some modifications^{12,17}. The kinetics of fluorescence change were monitored every minute for 25 min. Optimal concentrations for 3CL^{pro} and substrate were 150 nM and 600 nM respectively. A previously reported 3CL^{pro} inhibitor¹⁴, **ML188**, was used as a positive control for inhibition, both control and test compounds were titrated in the concentration range of 0.01 μM – 200 μM. Initial slopes of RFU/min were converted to μM hydrolyzed substrate/min using a standard curve of HiLyte Fluor488 amine, TFA salt.

Biochemical data analysis. After subtraction of background fluorescence readings, values of Km and EC50 were obtained by fitting the experimental data with the Michaelis–Menten ($y = (V_{max} \cdot x) / (K_m + x)$) and the four

parameters logistic (4PL) equations ($y = \min + (\max - \min) / (1 + (x/EC50)^{\text{Hillslope}})$) respectively, using Graph-Pad Prism 8.

Dynamic scanning fluorimetry (DSF). Thermal unfolding of proteins was monitored in a 20 μ L volume in Micro-Amp EnduraPlate Optical 384-well Clear Reaction Plates (ThermoFisher: cat no. 4483285). Reactions contained 50 mM HEPES pH 7.5, 62.5 mM NaCl, 7 μ M 3CL^{pro} or PL^{pro}, 5% DMSO, and 4 $\times$ SYPRO-orange protein gel stain (ThermoFisher Scientific, Massachusetts, USA; cat no. S6651). Famotidine and the positive controls **ML188** and **compound 6** for 3CL^{pro} and PL^{pro}, respectively, were incubated with the protein for 15 min before the addition of SYPRO orange. Plates were covered with Micro-Amp Optical Adhesive Film (ThermoFisher Scientific, Massachusetts, USA; cat no. 4360954) and run on Applied Biosystems 7900HT (California, USA) real time PCR instrument. Samples were incubated at 25 °C for 2 min followed by an increase in temperature of 1 °C/min up to 95 °C. Fluorescence was monitored continuously. Each sample was run in triplicate and compounds were tested at 1 mM, 2.5 mM, and 5 mM. The melting temperature (T_m) was obtained from the first derivative of the raw thermal denaturing data were determined and smoothed to calculate melting temperature (T_m) values⁴⁰.

Surface plasmon resonance (SPR). SPR studies were performed on a Biacore 3000 instrument (Cytiva, Massachusetts, USA) at 10 °C. The PL^{pro} and 3CL^{pro} proteins were biotinylated by minimal biotinylation approach with the EZ-LINK Sulfo-NHS-LC-LC-biotin reagent (ThermoFisher Scientific, Massachusetts, USA; cat no. A35358) and immobilized on a neutravidin coated CM5 sensor chip to a level of 4000 response units (RU). The protein used during immobilization was at 1 μ M for PL^{pro} and 1 μ M for 3CL^{pro}. During the course of the assay different concentrations of compounds were injected. The Compounds were serially diluted (twofold) in a running buffer of 25 mM HEPES pH 7.0, 200 mM NaCl, 2 mM TCEP, 0.005% P20 and 1% DMSO. Famotidine, and the control inhibitors, **compound 6** and the **ML188** were tested up to a maximal dose of 100 μ M, 50 μ M and 5 μ M, respectively. The final response was obtained by subtracting the blank channel (without protein) and a buffer injection across the sample channel. Raw data were analyzed in the Scrubber2 program (BioLogic Software) by fitting the data to a simple 1:1 equilibrium and kinetic model.

Antiviral assays. *Viruses and titration.* Virus infectivity assays were carried out using the 2019-nCoV/USA-WA1/2020 isolate of SARS-CoV-2 (NCBI accession number: MN985325), obtained from the Centers for Disease Control and Prevention and BEI Resources (Virginia, USA). The virus stock was propagated in Vero E6 cells and virus titers determined using plaque formation assays, as described previously⁴¹.

Antiviral assays. Human lung A549 cells expressing SARS-CoV-2 entry factors and African Green Monkey kidney Vero E6 cells were maintained in DMEM supplemented with 10% fetal bovine serum (FBS). The cells were seeded into poly-L-lysine-coated 96-well plates at a density of 15,000 cells per well. The cells were then treated for 4 h with five-fold serial dilutions of famotidine, ranging between 0.32 μ M and 200 μ M. DMSO served as a negative control, while fivefold serial dilutions of remdesivir, ranging between 0.1 μ M and 62.5 μ M, served as a positive control. The cells were then infected with SARS-CoV-2 at a multiplicity of infection (MOI) of 0.1. To infect cells, the compound-containing medium was removed, and the cells were incubated with the virus for 1 h at 37 °C. The virus inoculum was then removed, and the cell monolayer was rinsed twice with 1X PBS. The compounds were added back followed by incubation for 72 h, after which the cell culture medium was harvested for quantitative real-time PCR (qRT-PCR) and plaque assays, while the cells were fixed with 4% paraformaldehyde for immunofluorescence microscopy.

Virus RNA extraction and quantitative real-time PCR (qRT-PCR). RNA was isolated from the cell culture supernatant of SARS-CoV-2-infected cells using the Quick-RNA Viral Kit (Zymo, California, USA cat no. R1035) according to the manufacturer's instructions. Viral RNA was quantified using single-step RT-quantitative real-time PCR using the qScript One-Step RT-qPCR Kit (Quantabio, Massachusetts, USA; cat no. 95058) with primers and Taqman probes targeting the SARS-CoV-2 E gene as previously described⁴². Data were acquired using a Quantstudio3 Real-Time PCR System (Applied Biosystems) using the following conditions: 55 °C for 10 min, denaturation at 94 °C for 3 min, 45 cycles of denaturation at 94 °C for 15 s, and annealing at 58 °C for 30 s. The primers and probe used were as follow: E_Sarbeco_Forward: ACAGGTACGTTAATAGTTAATAGCGT; E_Sarbeco_Probe: FAM-ACACTAGCCATCCTTACTGCGCTTCG-BBQ; E_Sarbeco_Reverse: ATATTGCAGCAGTACGCACACA. For absolute quantification of viral RNA, a 389 bp fragment from the SARS-CoV-2 E gene was cloned onto pIDTBlue plasmid under an SP6 promoter using NEB PCR cloning kit (New England Biosciences, Massachusetts, USA; cat no. E1202S). The cloned fragment was then *in-vitro* transcribed using the mMessage mMachine SP6 transcription kit (ThermoFisher, Massachusetts, USA; cat no. AM1340) to generate the qRT-PCR standard.

Immunofluorescence microscopy. Virus-infected cells were fixed with 4% paraformaldehyde for 30 min. The fixative was removed, and the cell monolayer washed twice with 1X PBS. The cells were then permeabilized and stained with an anti-SARS-CoV Nucleocapsid (N) antibody (Rockland Inc., Pennsylvania, USA; cat. no. 200–401-A50; 1:2,000 dilution). Incubation with the primary antibody was performed overnight at 4 °C. The cells were then washed 5 times with 1X PBS and stained with Alexa 568-conjugated anti-rabbit antibody (1:1000 dilution) in the dark at room temperature for 1 h and counterstained with DAPI. Images were captured using EVOS M5000 Imaging System (ThermoFisher Scientific, Massachusetts, USA). Quantitation and analysis of the fixed cell images was carried out using the MuviCyte Live-Cell Imaging System (PerkinElmer, Massachusetts,

USA). At least 7–10 microscopic fields were imaged per well using a 10X objective lens, the number of cells positive for the SARS-CoV-2 N protein and the nuclear DAPI stain, were counted. For each image, the percentage of DAPI-positive cells expressing the viral N protein were calculated, and the mean $\pm$ SD of multiple images for each condition was plotted.

Cytotoxicity/cell viability assay. The CellTiter-Glo Luminescent Cell Viability Assay (Promega, Wisconsin, USA; cat no. G7570) was used to determine the cytotoxic effects of the compounds. Briefly, the cells were incubated with five-fold serial dilutions of famotidine or remdesivir for 72 h, after which the CellTiter-Glo Reagent was added to each well in a volume equal to the volume of the culture medium. The contents were mixed by shaking the plate on an orbital shaker for 2 min, followed by a 10 min incubation at room temperature. Luminescence was recorded using a Varioskan LUX multimode plate reader (ThermoFisher Scientific, Massachusetts, USA).

Data availability
